The third and most important obstacle is situated at the neck of the bladder, and is dependent upon the narrow tense ring beyond the prostate which remains intact in spite of the dilatation and laceration to which the prostate has been subjected. I have found, by experiments on the dead body, that this inner ring of the neck of the bladder cannot be expanded to a size more than sufficient for the extraction of a calculus of one inch in diameter without laceration or incision : and its laceration or rupture is well known to be one of the most dangerous and fatal accidents in lithotomy. A calculus over one and a half inches in diameter cannot be extracted by the median operation without the employment of great violence. But, though much force is usually required in order to extract a calculus of even moderate size through this tense ring at the neck of the bladder, it is an undeniable fact that serious consequences seldom follow the violence so used, and that a degree of force, which would be fatal in lateral lithotomy, may be employed without danger in the extraction of a calculus by the median operation. In this respect the extraction of a calculus by the median operation resembles the removal of one through the dilated urethra of the female ; the great point in favour of the median over the lateral procedure, and the cause of its comparative safety, being that the lateral true ligament of the bladder is not incised, nor otherwise

opened. But, it may be said, what is easier, when the finger is in the bladder, than to push a probe-pointed bistoury along it, and cut downwards and outwards through these structures into the ischio-rectal fossa, if the stone be large, and thus get plenty of space? Nothing could be easier or more simple; but what would be the consequence? We at once reduce the median to the conditions of the lateral operation. A free incision in the neck of the bladder and prostate increases the tendency to hæmorrhage, opens up the fascia, and exposes the patient, in fact, to all the dangers of an ill-contrived lateral operation, destroying at once and altogether the principle of the median operation—viz., dilatation and not incision; and, if we do not gain space by incision, but attempt to extract a moderately large stone by dilatation of the parts, we shall certainly not succeed, but our dilatation will end in a laceration, not only of the substance of the prostate, which is safe, but of the neck and perhaps of the base of the bladder, which will be fatal.

Mortality.—It is not easy to determine the death-rate following this operation, as the results are generally included with other methods of perinæal lithotomy. Barling has collected 48 operations performed between 1888 and 1892; of these 6 died, giving a mortality of 12·5 per cent.

OTHER METHODS OF PERFORMING LITHOTOMY.—Having fully described the suprapubic, lateral, and median operations of lithotomy, it remains only to mention very briefly certain other methods which have been adopted, but which at the present day have been almost, if not entirely, discarded.

Bilateral Lithotomy.—This operation, which was introduced by Dupuytren, consisted in making a curved transverse incision with its concavity backwards half an inch in front of the anus. The dissection was carried down to the central point of the perinæum and the membranous urethra opened on a grooved median staff. Along this a *lithotome caché* was passed, which divided both lateral lobes of the prostate in a direction downwards and outwards. The stone was then extracted in the usual way.

Medio-Bilateral Lithotomy was recommended by Civiale for the extraction of stones too large for the ordinary median operation. It consisted of a combination of the median and bilateral. The membranous part of the urethra was opened on a rectangular staff as in the median operation. The lithotome was then introduced and the prostate and the soft structures between it and the surface incised. If the stone was not very large, the deep incision was confined to one side only, and used with a probe-pointed bistoury.

Recto-vesical Lithotomy was suggested by Sanson in 1847 as a means of removing large stones and avoiding the dangers of hæmorrhage. It was thus performed. A staff grooved on its convexity was passed into the bladder, the finger was then passed into the rectum, and the part of the staff lying in the membranous portion of the urethra felt for; a knife, with its edge directed forwards, was then passed along the finger into the groove of the staff and withdrawn, dividing the internal and external sphincters and the skin at the margin of the anus; it was then reintroduced with its edge directed downwards, and run along the groove of the staff, dividing the prostate and notching the neck of the bladder, and the stone was then extracted in the usual way.

Having now described the various operations of lithotomy it will be convenient to reserve the consideration of the relative advantages of the principal methods until after the operation of Lithotrity has been described in the following Chapter.

CHAPTER LXVIII.

URINARY CALCULUS (*continued*).

LITHOTRITY.

THE operation of **Lithotrity**, by which the stone is crushed in the bladder and the fragments expelled or extracted through the urethra, is of modern invention ; for, though various rude attempts may at different times have been made with this view, it was not until about the year 1818 or 1820 that the subject began to attract serious attention ; and to the French Surgeons is undoubtedly due the great merit of having introduced this operation. About this time Civiale, followed by Amussat, Leroy, and others, began constructing instruments, which, though very imperfect, yet were sufficient to break down a calculus in the bladder. This was publicly done by Civiale in 1822. From this period lithotrity made rapid progress ; and the successive improvements made by the Surgeons whose names have just been mentioned, together with the ingenious mechanical adaptations introduced by Charrière and Weiss, enabled Surgeons to attack the stone with certainty and effect.

The importance of lithotrity was urged upon the profession by Civiale, Amussat and Heurteloup in France and Brodie and Costello in this country. The practice thus established by these Surgeons has from time to time been improved by the ingenuity of others, amongst whom Fergusson, Coulson and Thompson are conspicuous. Up to the year 1878 the operation of lithotrity was practised on the lines originally laid down by Civiale and Brodie, the main features of which were to crush the stone by repeated operations, each limited to a few minutes, and to allow the fragments to be passed by the natural efforts of the patient. In 1878, however, Bigelow of Boston demonstrated that it was possible to break the stone up at one prolonged operation, and completely to wash out the fragments at the same time through a large catheter or evacuator. To this method of operating he gave the name of "Litholapaxy," but its enormous advantage over the older methods was so quickly recognized, and it so speedily became universally adopted, that the distinctive name is now unnecessary, and when we speak of lithotrity we mean crushing the stone and removing the fragments at the same time by Bigelow's method. By this great improvement Bigelow not only reduced the sufferings of the patient and the dangers of the operation, but made it applicable to much larger stones than could possibly be removed by the older method.

Instruments.—The instruments required for lithotrity are the following :

An ordinary **sound** with a short beak is required to examine the condition of the bladder. The steel sound should be hollow, so that the bladder may, if necessary, be injected through it after or during sounding, without the necessity of changing the instrument (Fig. 872). This will be found of much service in the later stages of the operation for detecting small fragments.

A **brass syringe** should be at hand with which the bladder may be injected if necessary.

An Otis's **Urethrometer** is often useful, by which the size of the passage can be measured as a guide to the evacuator to be used.

Some large-sized **conical steel bougies**, from 12 to 18 of the English scale, are of great use in measuring and dilating the passage before inserting the lithotrite or the large evacuator.

The instrument for breaking the stone is called a **lithotrite**. This has

Fig. 872.—Lithometer Sound for measuring Stone. It is hollow, so that the bladder can be emptied and injected through it.

undergone various modifications and improvements at the hands of Mechanics and Surgeons. To Weiss in this country, and to Charrière in France, we are especially indebted for having brought it to its present state of perfection. In the earlier days of lithotrity Weiss's thumb-screw lithotrite was generally used. Fergusson invented a rack-and-pinion instrument,

Fig. 873.—Civiale's Lithotrite for Crushing Fragments.

which, however, found little favour with Surgeons. Civiale's instruments, having the double action of screw and hand pressure, were those to which many gave the preference until the invention of the cylindrical handle by Thompson.

The lithotrite must be made of well-tempered steel ; and should be tested

Fig. 874.—Position of Hand in using Civiale's Lithotrite.

by being made to crush a piece of sandstone grit, of about the size of a walnut. It should be of as full a size as the urethra will readily admit ; it must have the male blade well serrated, and the female or under blade pierced at its root by an oval aperture, through which the detritus of the crushed stone is forced, and thus any jamming of it in the angle between the blades is prevented. The female blade should be considerably wider than the male to avoid nipping of the mucous membrane of the bladder.

The larger lithotrites, intended to break stones of considerable size, are made with a fenestra in the female blade; those intended to crush small fragments with a broad blade without a fenestra.

The lithotrite should be cut out of a bar of solid steel, and not, as is the

Fig. 875.—Thompson's Improved Lithotrite.

case with some instruments, made of a plate of this metal, turned up at the edges; as such a one possesses too little strength to be used with safety on large and hard calculi.

Civiale's lithotrite, such as is represented in Fig. 873, has a most ingenious

Figs. 876, 877, 878, 879.—Bigelow's Lithotrite.

double action, enabling the Surgeon to work it either by the pressure of the hand or by a screw. In this instrument, there is no fenestra in the female blade. It is of two kinds. In one, the male blade is much narrower than the female; in the other, it is nearly as broad. The first kind is useful in

crushing through moderate-sized stones; the second kind, with the broad male blade, is used in completely crushing and removing the detritus of small calculi, and the large fragments into which a stone has been broken by the open-bladed lithotrite.

Thompson's lithotrite (Fig. 875) somewhat resembles Civiale's in its action, but is more handy. The handle of the female blade is round, which gives the operator a better grasp of the instrument, and the sliding movement is converted into a screw action by drawing up the button on the handle with

Fig. 860.—Clover's Lithotritry Injection-Apparatus. 1. Elastic Stylet for Lithotritry Catheter. 2, 3, 4, 5. Lithotritry Catheters with large eyes at end or in different sides, to be used with or without the Injection Apparatus.

the thumb of the right hand without relaxing the grasp of the left on the handle.

Bigelow introduced several modifications in the lithotrite. For large stones he had constructed instruments larger, heavier, and more powerful than any previously in use. The handles are large and massive, and oval in form to fit the hand (Figs. 876, 877). The blades are somewhat longer, and the female blade has a long blunted point, curved towards the floor of the urethra, so as to protect the membranous part, against the roof of which the point of the instrument is directed as it passes through (Figs. 878, 879). The sliding is converted into the screw movement by twisting the cap shown in the figure with the right hand. These very massive instruments are only required for large

and hard stones which it would formerly have been considered unwise to crush. For smaller stones Bigelow uses instruments of the ordinary size.

After the stone has been crushed the **evacuator** is required to remove the fragments. This consists essentially of a powerful india-rubber bottle which

Bigelow's Catheters, Full Size.

Fig. 881.—Bigelow's Straight Catheter.

Fig. 882.—Bigelow's Curved Catheter

can be connected with a large catheter. The bottle is emptied into the bladder by squeezing, and when the pressure of the hand is removed it sucks the fluid back with considerable force, bringing out at the same time the

Fig. 883.—Removal of fragments of Stone by Bigelow's original Evacuator. Below, point of one of Bigelow's Catheters.

crushed fragments of the stone. In all forms of evacuator a glass vessel is attached to the lowest part of the bottle, into which the fragments gravitate. Clover's simple instrument (Fig. 880) may be considered the parent of the evacuators now in use. It was provided with a number of catheters open at the end or having large eyes. When passing the open-ended catheter a gum

elastic stylet with a round metal point was introduced. The instrument was intended to wash out the detritus and smaller fragments after each operation, but did not meet with the favour it deserved, partly owing to its inefficiency from the weakness of the rubber bottle commonly provided.

In Bigelow's instrument the catheters are much larger than in Clover's, No. 29 French (18 English) being the largest size. The eye is very large and

Fig. 885.—Bigelow's Evacuator

is placed in the front of the instrument close to the end. The catheters are of different forms, the most convenient being one with a short curve like that of a sound. A perfectly straight instrument is also often very useful, and is preferred by Bigelow.

The actual size and shape of the evacuating catheters most commonly used are shown in Figs. 881 and 882.

The various modifications of the evacuator are represented in the accompanying figures. Fig. 883 represents Bigelow's original evacuator, which he, however, abandoned for the improved form represented in Fig. 885. By

connecting the air-pipe attached with the evacuator and fixing the india-rubber tube around it. Fig. 884 is the cock at the apex of the bottle, the contents may be expelled and fresh water drawn in without disconnecting the bottle from the evacuator. I have to thank Professor Bigelow for furnishing me with the accompanying woodcuts, which represent the main instruments used by

Fig. 886.—Mr H. Thompson's Improved Evacuator.

himself. Modifications of Bigelow's evacuator suggested by Thompson and Otis are shown in Figs. 886 and 887.

Preparation of the Patient.—Before proceeding to the operation of lithotrity, it is necessary that the patient's constitution should be carefully attended to; the bowels should be freely opened, and the condition of the digestive organs regulated, and, more especially, all local irritability about the urinary organs should be subdued by ordinary medical treatment. This is even of greater importance than in lithotomy, as the prolonged mechanical disturbance to which the bladder is exposed may aggravate any existing cystitis. The urine should be carefully examined, and the condition of the kidneys ascertained as far as possible. In a subsequent part of this Chapter, when we come to the comparison of lithotomy and lithotrity, we shall examine the conditions which either indicate or negative the performance of the latter operation. At present, we will suppose a case in which the Surgeon may have recourse to lithotrity, with every prospect of readily and

Fig. 887.—Otis's Evacuator.

permanently ridding the patient of his calculus.

Use of Anæsthetics.—In former times many Surgeons habitually performed the operation without an anæsthetic, believing that the sensations of the patient were a useful guide to the Surgeon, helping him to avoid nipping or otherwise injuring the bladder. For the success of the present method of

operating an anæsthetic is essential, both to enable the Surgeon to continue the operation till the stone is completely crushed, and to facilitate the subsequent washing out of the fragments.

Operation.—The operation of lithotripsy may be divided into four stages : 1. The introduction of the lithotrite ; 2. The search for and seizure of the stone ; 3. The crushing of the stone ; and 4. The evacuation of the fragments.

As a preliminary step before the operation, Bigelow recommends that the urethra be measured with Otis's urethrometer, in order to ascertain the size of the evacuator that should be used. Thompson recommends the passage of a large conical steel bougie, which answers the same purpose, and at the same time slightly dilates the canal. The bougies passed should be from Nos. 14 to 18 of the English scale at the thickest part. With a urethra admitting No. 16 no difficulty need be anticipated in the operation, even if the stone is large. If the orifice is too narrow to admit this, it should at once be divided with a probe-pointed bistoury.

1. **Introduction of the Lithotrite.**—If the size of the stone is known,

Fig. 888.—Introduction of the Lithotrite.

the lithotrite must be adapted to it. If it be large and probably hard, a full-sized, fenestrated lithotrite should first be passed, with which the calculus may be broken into several small fragments. After this it may be withdrawn, and a smaller non-fenestrated instrument used to complete the crushing.

The operation may most conveniently be performed with the patient lying on his back upon a flat table close to its right edge. The pelvis must be raised by a hard pillow, so as to allow the stone to roll up on the posterior surface of the bladder. The Surgeon, standing on the right side of the patient, carefully introduces the hollow sound, or catheter, and draws off the urine ; he then slowly and very cautiously injects the bladder, by means of

the brass syringe, with from four to six ounces of some antiseptic solution, such as boric acid lotion. The use of drawing off the urine is to make sure of the bladder holding the proper quantity of fluid when it is afterwards injected; and the object in injecting it, is to distend it to such an extent as to prevent the mucous membrane from being seized in the grasp of the lithotrite, or injured by the splintering of the stone. The instrument is then withdrawn, after the situation of the stone has been detected by it, and the lithotrite is introduced. Should the patient be able to hold enough urine, viz., from three to four ounces, to protect his bladder from the action of the lithotrite or the fragments, the injection may be dispensed with, and the lithotrite may be used at once. As this is straight, with a sharp elbow near the beak, some little skill is required in passing it. In doing this the Surgeon must keep his eye upon the short curved beak of the instrument, the direction and position of which must constantly be judged of; and especial care must

.

Fig. 389.—Brodie's Method of Seizing the Stone.

be taken, in carrying it under the pubes, not to injure the urethra by pushing the beak of the lithotrite forwards too suddenly, instead of winding it, as it were, under the arch of that bone. The instrument should first be introduced nearly parallel to the abdomen, the penis being held between the fore and middle fingers, and drawn over it. As the lithotrite passes down, it must be gradually raised to the perpendicular position; and as its curve passes under the pubes, the handle should be depressed between the thighs (Fig. 388). The direction of the curve must be borne in mind, and the position of the handle varied in accordance with the course which this takes. No force must on any account be used. The weight of the handle is quite sufficient to make the instrument enter the bladder. The lithotrite should be well greased with carbolized oil, so that the blades and screw may work smoothly.

2. Seizure of the Stone.—The next point is to seize the stone, which will generally be found in the situation where its presence was detected during the sounding of the bladder. If large, the stone will probably lie low, near the neck of the bladder; if small, it is most frequently met with at the inferior

fundus. In seizing the calculus a good deal of tact may be required. The plan recommended by Brodie should first be adopted. The closed lithotrite is pressed gently against the inferior fundus of the bladder, so as to make a conical depression in this situation. The male blade is then gently withdrawn till some slight sense of resistance is felt, indicating that it is touching the other side of the bladder. A gentle shake may then be given to the handle, and the blades closed, when, in a large proportion of cases, the stone will be found to be between them (Fig. 889). During the whole of this proceeding the left hand, holding the instrument, must be kept perfectly steady, and no force of any kind should be used. If the stone is not at once grasped in this way, the manœuvre must be repeated, turning the blades slightly first to one side and then to the other. If this does not succeed, the plan recommended by Civiale may be tried: The closed lithotrite is used as a sound, and the situation of the stone determined. The beak of the instrument is then very gently turned towards the opposite side of the bladder, and the blades opened. The open instrument is then turned back again to the side on which the

Fig. 890.—Civiale's Method of Seizing the Stone behind the Prostate.

stone lies, and the blades closed. If the stone is not seized by either of these plans, it is possible that it is lying in a pouch behind the prostate. To reach it in this situation the handle of the lithotrite must be depressed between the patient's thighs, and the instrument turned round, so that the beak is directed towards the floor of the bladder (Fig. 890). It may then be carefully opened and closed again. This manœuvre is very frequently necessary in patients above 60, in order to crush the last fragments towards the end of the operation. If the stone be round and smooth it may be grasped only after many failures; the calculus slipping away between the blades of the instrument, and being merely scraped by them.

The essential conditions during this stage of the operation are that the utmost gentleness be used in all movements of the lithotrite, that the female blade be kept as steady as possible with the left hand, while the instrument is opened and shut by moving the male blade only, which, from its lightness, can be manipulated with great delicacy, and lastly, that the operator should picture to himself with each movement of the instrument the exact position in which the blades are placed.

~~Something like this~~— It is not in the way of the stone, but in the way of the instrument. The blades of the instrument may then be opened, and a fragment of the stone which is seized and crushed in the blades may be removed; and thus the complete disintegration of the stone is gradually effected.

Fig. 10. A view of the lithotrite in the bladder.

If a large *lithotrite* has been used, it must be withdrawn as soon as the stone has been broken into fragments of moderate size, and the smaller *lithotrite* instrument passed to complete the crushing. This should not be removed from the bladder, if possible, till from the impossibility of catching any definite fragments it may be hoped that the whole calculus is thoroughly crushed. Repeated withdrawal and reintroduction of the lithotrite wastes time and increases the risk of bruising the urethra and prostate. Before withdrawing the lithotrite, the Surgeon must be careful to see, by the scale on the handle, that the male blade is well home. If this be not the case, and the instrument be enlarged by any fragments or detritus entangled between the blades, laceration of the neck of the bladder or urethra might occur in attempting to withdraw it. If the blades do not close perfectly, the screw must be forcibly turned, and if that fails the female blade must be held very firmly with the left hand, while the male blade is unlocked, and rapped sharply upon it two or three times; this will usually dislodge any fragments between the blades.

4. The last stage of the operation consists in **Removing the Fragments by means of the Evacuator**. For this purpose an evacuating catheter (Figs. 881, 882, p. 1080) is passed into the bladder. This should be the largest the urethra will safely admit. This has already been determined by measurement with the urethrometer or conical sound. Bigelow generally uses No. 29 French (18 English), but Thompson states that he seldom finds it necessary to exceed No. 15 or 16 of the English scale. Bigelow prefers the straight instrument (Fig. 881), but the curved catheters usually pass more easily. Firm pressure is commonly required to pass the catheter, but no undue force must be used. It is better to use a smaller size than to run the risk of injuring the urethra by attempting to force in a larger instrument than it can safely take. The catheter having been passed, the bladder is completely emptied; the fluid that escapes being caught in a vessel and strained through muslin to collect any fragments of the stone that it may contain. It is essential that the india-rubber bulb should be of sufficient strength; otherwise the regurgitant stream will not be sufficiently forcible to withdraw any but the smallest fragments from the bladder. The fluid in the bottle should always contain some antiseptic: boric acid is perhaps the best. The evacuator, previously filled, having been attached to the catheter, by alternately compressing and relaxing the rubber bulb of the instrument the bladder is filled and emptied. At each injection the fragments are thrown up. At each relaxation of the bulb, some are sucked out in the rush of water. These drop into the glass receiver, where they can be seen by the Surgeon, who thus judges of the progress he is making. This process is continued until all fragments are evacuated. Should some have been left behind, too large to pass through the evacuating catheter, the lithotrite must again be introduced, and these broken up sufficiently for evacuation, which must then be resumed and continued until the bladder is emptied of all calculus. The Surgeon knows when fragments are left behind too large to pass, by their falling against the eye of the catheter, blocking it, and thus preventing the return of water into the bulb of the evacuator, as shown by its failing to expand. This may arise also from the eye of the instrument having come in contact with the wall of the bladder, or from the catheter having been accidentally withdrawn till its end lies in the prostatic urethra. Before concluding that the obstruction is due to a fragment, these two conditions must be excluded, by pushing the catheter a little further in and rotating it. A more certain sign of a fragment is a loud and distinct click every time the bulb is allowed to expand.

The removal of every fragment is the essence of Bigelow's operation. No stone must be left behind. The operation should be concluded at one sitting, however prolonged.

The **Time Occupied by the Operation** varies with the size of the stone and the ease with which the fragments are caught. Before Bigelow demonstrated the safety of prolonged operations under anaesthetics, the strictest rules were laid down as to the duration of the sitting. The first was not to exceed four minutes, and it was considered sufficient to break up the stone, leaving the fragments to be dealt with subsequently. The subsequent sittings were also limited to a few minutes. The sittings were repeated every three or four days till the whole stone was broken up, a longer or shorter interval being allowed according to the amount of irritation caused by the operation. It was

only in the case of a very small stone that the operation was finished at one sitting. At the present time the crushing is completed in all but very exceptional cases at one sitting, and the results of the practice have shown that the irritation caused by a prolonged operation carefully performed is infinitely less than that set up by a mass of sharp fragments such as are left after partial crushing of a stone. If the stone is of any size an hour or an hour and a half may be occupied in completely crushing it. The longest time that Thompson has occupied in an operation at a single sitting has been 70 minutes. This was in the case of an unusually hard uric acid calculus weighing $2\frac{3}{4}$ ounces. In a case recorded by Surgeon-Major Keegan, of Indore, the stone weighed $3\frac{1}{2}$ ounces, and was at first too large to be grasped by the lithotrite, but by gradually nibbling at it he reduced it till it could be fairly seized and crushed. The operation lasted four hours, but the patient went home well on the fourth day. In the performance of prolonged operations at a single sitting Thompson enjoins the very important caution that the patient's lower extremities should be encased in long woollen stockings, and that especial care be taken to prevent his getting chilled by exposure.

After-Treatment of Lithotritry.—After the operation a half-grain morphia suppository should be administered and the patient put to bed with a hot fomentation over the lower part of the abdomen. If the operation has for any reason been incomplete he should pass water lying on his back lest any fragments should be washed on and lodge in the urethra. When the operation is complete this precaution is not necessary. In very rare cases some retention of urine may follow owing to slight swelling of the neck of the bladder, necessitating the passage of a soft catheter. The diet should be chiefly milk and barley-water for a few days, and if any stimulant is required Hollands and barley-water is the best. The slight cystitis that usually follows the operation requires no special treatment. If there is much irritability of the bladder, hyoscyamus is often of use. If the cystitis is more severe it must be treated as described in the Chapter on Diseases of the Bladder.

Complications in Lithotritry. Size of the Stone.—Before the invention of rapid lithotritry with evacuation no stone over one inch and a half was considered suited to lithotritry. At the present time any stone that can be grasped in the blades of the lithotrite, and is not too hard to be broken, may be removed by this method. It must be remembered, however, that a large stone necessarily means a long operation, and in very old or weak patients, and especially in those suffering from chronic bronchitis and emphysema, two hours under an anæsthetic is accompanied by considerable danger. In such cases, possibly, a better chance of life would be given by suprapubic lithotomy.

Cystitis before the Operation need not prevent its performance if the stone is small. The removal of the source of irritation, and the washing out of the foul mucus with the evacuator, will often bring immediate relief. If the stone be large, and the cystitis acute, lithotomy would probably give the best chance if the condition of the patient renders some interference urgently necessary.

Chronic Enlargement of the Prostate was formerly one of the most serious complications of the operation of lithotritry, not so much from the difficulty it caused in the introduction of instruments as from the obstacle it offered to the expulsion of the fragments. With the present

evacuators, however, moderate enlargement of the prostate can scarcely be termed an inconvenience. When the prostate is enlarged, the stone, if small, or the fragments after the first crushing, fall into a pouch behind the neck of the bladder, and it is then impossible to seize them except by reversing the blades in the manner already described (p. 1085). When the stone is seized the blades must be carefully turned into the ordinary position before it is crushed. In such cases Buckston Browne has found the introduction of the rectal bag (p. 1044) useful as a means of preventing the fragments falling into the pocket behind the prostate.

In cases of extreme enlargement lithotritry may be impossible, as the lithotrite may not be able to enter the bladder, or if it can be introduced its blades may be too short to reach the stone in the pouch behind the middle lobe. In such cases suprapubic lithotomy is the preferable operation.

Stricture of the Urethra, if it can be dilated to a size sufficient to admit the necessary instruments, is not a serious complication in lithotomy at a single sitting. In former times it was considered an almost insuperable obstacle to the operation from the obstruction it offered to the expulsion of the fragments.

Sacculation of the Bladder is a most serious complication, the existence of which we have unfortunately no means of determining before the operation. The fragments are very apt to fall into the sacculi, from which they are with difficulty dislodged by the evacuator. If they are left they may cause recurrence of the stone in the bladder, or give rise to encysted sacculi. If septic cystitis follows, it is possible that a fragment lodged in a sacculus might lead to ulceration and perforation.

Accidents during Lithotritry can hardly arise except from carelessness or the use of improper force. The large instruments can scarcely make false passages, unless used with great violence; yet I have known of a case in which the beak of the instrument was driven through the urethra into the space between the bladder and the pubes by too early and forcible depression of the handle. Nipping the coats of the bladder is almost impossible with the instruments now in use. Bending or breaking of the lithotrite can scarcely occur if the instrument has been properly tested before being used. Jamming of the instrument by a hard fragment becoming wedged in the angle between the male and female blades where they join the shaft is practically impossible with the modern instruments. If it should happen, the bladder may be opened in the perinæum using the lithotrite as a staff, and the blades brought out and freed, or they may be exposed by suprapubic cystotomy, and cleared or cut off with a file according to circumstances.

Accidents after the Operation.—**Hæmorrhage** is a rare occurrence. Should the bladder become filled with clots they may easily be removed by reintroducing the evacuating catheter and sucking them out with the evacuator, or by the introduction of a large sized gum-elastic catheter, to which an aspirator may be applied.

Impaction of Angular Fragments of Stone in the Urethra.—This most dangerous and painful accident was not uncommon in the old system of lithotritry. In modern lithotritry it can happen only if a large fragment has been accidentally left behind or if from any cause the operation has to be left incomplete. If there is any reason to believe that fragments are left in the bladder the patient must be kept in a recumbent position, as impaction

only in the case of a very small stone that the operation was finished at one sitting. At the present time the crushing is completed in all but very exceptional cases at one sitting, and the results of the practice have shown that the irritation caused by a prolonged operation carefully performed is infinitely less than that set up by a mass of sharp fragments such as are left after partial crushing of a stone. If the stone is of any size an hour or an hour and a half may be occupied in completely crushing it. The longest time that Thompson has occupied in an operation at a single sitting has been 70 minutes. This was in the case of an unusually hard uric acid calculus weighing $2\frac{3}{4}$ ounces. In a case recorded by Surgeon-Major Keegan, of Indore, the stone weighed $3\frac{1}{2}$ ounces, and was at first too large to be grasped by the lithotrite, but by gradually nibbling at it he reduced it till it could be fairly seized and crushed. The operation lasted four hours, but the patient went home well on the fourth day. In the performance of prolonged operations at a single sitting Thompson enjoins the very important caution that the patient's lower extremities should be encased in long woollen stockings, and that especial care be taken to prevent his getting chilled by exposure.

After-Treatment of Lithotritry.—After the operation a half-grain morphia suppository should be administered and the patient put to bed with a hot fomentation over the lower part of the abdomen. If the operation has for any reason been incomplete he should pass water lying on his back lest any fragments should be washed on and lodge in the urethra. When the operation is complete this precaution is not necessary. In very rare cases some retention of urine may follow owing to slight swelling of the neck of the bladder, necessitating the passage of a soft catheter. The diet should be chiefly milk and barley-water for a few days, and if any stimulant is required Hollands and barley-water is the best. The slight cystitis that usually follows the operation requires no special treatment. If there is much irritability of the bladder, hyoscyamus is often of use. If the cystitis is more severe it must be treated as described in the Chapter on Diseases of the Bladder.

Complications in Lithotritry. Size of the Stone.—Before the invention of rapid lithotritry with evacuation no stone over one inch and a half was considered suited to lithotritry. At the present time any stone that can be grasped in the blades of the lithotrite, and is not too hard to be broken, may be removed by this method. It must be remembered, however, that a large stone necessarily means a long operation, and in very old or weak patients, and especially in those suffering from chronic bronchitis and emphysema, two hours under an anæsthetic is accompanied by considerable danger. In such cases, possibly, a better chance of life would be given by suprapubic lithotomy.

Cystitis before the Operation need not prevent its performance if the stone is small. The removal of the source of irritation, and the washing out of the foul mucus with the evacuator, will often bring immediate relief. If the stone be large, and the cystitis acute, lithotomy would probably give the best chance if the condition of the patient renders some interference urgently necessary.

Chronic Enlargement of the Prostate was formerly one of the most serious complications of the operation of lithotritry, not so much from the difficulty it caused in the introduction of instruments as from the obstacle it offered to the expulsion of the fragments. With the present

evacuators, however, moderate enlargement of the prostate can scarcely be termed an inconvenience. When the prostate is enlarged, the stone, if small, or the fragments after the first crushing, fall into a pouch behind the neck of the bladder, and it is then impossible to seize them except by reversing the blades in the manner already described (p. 1085). When the stone is seized the blades must be carefully turned into the ordinary position before it is crushed. In such cases Buckston Browne has found the introduction of the rectal bag (p. 1044) useful as a means of preventing the fragments falling into the pocket behind the prostate.

In cases of extreme enlargement lithotritry may be impossible, as the lithotrite may not be able to enter the bladder, or if it can be introduced its blades may be too short to reach the stone in the pouch behind the middle lobe. In such cases suprapubic lithotomy is the preferable operation.

Stricture of the Urethra, if it can be dilated to a size sufficient to admit the necessary instruments, is not a serious complication in lithotomy at a single sitting. In former times it was considered an almost insuperable obstacle to the operation from the obstruction it offered to the expulsion of the fragments.

Sacculation of the Bladder is a most serious complication, the existence of which we have unfortunately no means of determining before the operation. The fragments are very apt to fall into the sacculi, from which they are with difficulty dislodged by the evacuator. If they are left they may cause recurrence of the stone in the bladder, or give rise to encysted sacculi. If septic cystitis follows, it is possible that a fragment lodged in a sacculus might lead to ulceration and perforation.

Accidents during Lithotritry can hardly arise except from carelessness or the use of improper force. The large instruments can scarcely make false passages, unless used with great violence; yet I have known of a case in which the beak of the instrument was driven through the urethra into the space between the bladder and the pubes by too early and forcible depression of the handle. Nipping the coats of the bladder is almost impossible with the instruments now in use. Bending or breaking of the lithotrite can scarcely occur if the instrument has been properly tested before being used. Jamming of the instrument by a hard fragment becoming wedged in the angle between the male and female blades where they join the shaft is practically impossible with the modern instruments. If it should happen, the bladder may be opened in the perinæum using the lithotrite as a staff, and the blades brought out and freed, or they may be exposed by suprapubic cystotomy, and cleared or cut off with a file according to circumstances.

Accidents after the Operation.—**Hæmorrhage** is a rare occurrence. Should the bladder become filled with clots they may easily be removed by reintroducing the evacuating catheter and sucking them out with the evacuator, or by the introduction of a large sized gum-elastic catheter, to which an aspirator may be applied.

Impaction of Angular Fragments of Stone in the Urethra.—This most dangerous and painful accident was not uncommon in the old system of lithotritry. In modern lithotritry it can happen only if a large fragment has been accidentally left behind or if from any cause the operation has to be left incomplete. If there is any reason to believe that fragments are left in the bladder the patient must be kept in a recumbent position, as impaction

only in the case of a very small stone that the operation was finished at one sitting. At the present time the crushing is completed in all but very exceptional cases at one sitting, and the results of the practice have shown that the irritation caused by a prolonged operation carefully performed is infinitely less than that set up by a mass of sharp fragments such as are left after partial crushing of a stone. If the stone is of any size an hour or an hour and a half may be occupied in completely crushing it. The longest time that Thompson has occupied in an operation at a single sitting has been 70 minutes. This was in the case of an unusually hard uric acid calculus weighing $2\frac{3}{4}$ ounces. In a case recorded by Surgeon-Major Keegan, of Indore, the stone weighed $3\frac{1}{2}$ ounces, and was at first too large to be grasped by the lithotrite, but by gradually nibbling at it he reduced it till it could be fairly seized and crushed. The operation lasted four hours, but the patient went home well on the fourth day. In the performance of prolonged operations at a single sitting Thompson enjoins the very important caution that the patient's lower extremities should be encased in long woollen stockings, and that especial care be taken to prevent his getting chilled by exposure.

After-Treatment of Lithotrity.—After the operation a half-grain morphia suppository should be administered and the patient put to bed with a hot fomentation over the lower part of the abdomen. If the operation has for any reason been incomplete he should pass water lying on his back lest any fragments should be washed on and lodge in the urethra. When the operation is complete this precaution is not necessary. In very rare cases some retention of urine may follow owing to slight swelling of the neck of the bladder, necessitating the passage of a soft catheter. The diet should be chiefly milk and barley-water for a few days, and if any stimulant is required Hollands and barley-water is the best. The slight cystitis that usually follows the operation requires no special treatment. If there is much irritability of the bladder, hyoscyamus is often of use. If the cystitis is more severe it must be treated as described in the Chapter on Diseases of the Bladder.

Complications in Lithotrity. Size of the Stone.—Before the invention of rapid lithotrity with evacuation no stone over one inch and a half was considered suited to lithotrity. At the present time any stone that can be grasped in the blades of the lithotrite, and is not too hard to be broken, may be removed by this method. It must be remembered, however, that a large stone necessarily means a long operation, and in very old or weak patients, and especially in those suffering from chronic bronchitis and emphysema, two hours under an anæsthetic is accompanied by considerable danger. In such cases, possibly, a better chance of life would be given by suprapubic lithotomy.

Cystitis before the Operation need not prevent its performance if the stone is small. The removal of the source of irritation, and the washing out of the foul mucus with the evacuator, will often bring immediate relief. If the stone be large, and the cystitis acute, lithotomy would probably give the best chance if the condition of the patient renders some interference urgently necessary.

Chronic Enlargement of the Prostate was formerly one of the most serious complications of the operation of lithotrity, not so much from the difficulty it caused in the introduction of instruments as from the obstacle it offered to the expulsion of the fragments. With the present

evacuators, however, moderate enlargement of the prostate can scarcely be termed an inconvenience. When the prostate is enlarged, the stone, if small, or the fragments after the first crushing, fall into a pouch behind the neck of the bladder, and it is then impossible to seize them except by reversing the blades in the manner already described (p. 1085). When the stone is seized the blades must be carefully turned into the ordinary position before it is crushed. In such cases Buckston Browne has found the introduction of the rectal bag (p. 1044) useful as a means of preventing the fragments falling into the pocket behind the prostate.

In cases of extreme enlargement lithotritry may be impossible, as the lithotrite may not be able to enter the bladder, or if it can be introduced its blades may be too short to reach the stone in the pouch behind the middle lobe. In such cases suprapubic lithotomy is the preferable operation.

Stricture of the Urethra, if it can be dilated to a size sufficient to admit the necessary instruments, is not a serious complication in lithotomy at a single sitting. In former times it was considered an almost insuperable obstacle to the operation from the obstruction it offered to the expulsion of the fragments.

Sacculation of the Bladder is a most serious complication, the existence of which we have unfortunately no means of determining before the operation. The fragments are very apt to fall into the sacculi, from which they are with difficulty dislodged by the evacuator. If they are left they may cause recurrence of the stone in the bladder, or give rise to encysted sacculi. If septic cystitis follows, it is possible that a fragment lodged in a sacculus might lead to ulceration and perforation.

Accidents during Lithotritry can hardly arise except from carelessness or the use of improper force. The large instruments can scarcely make false passages, unless used with great violence; yet I have known of a case in which the beak of the instrument was driven through the urethra into the space between the bladder and the pubes by too early and forcible depression of the handle. Nipping the coats of the bladder is almost impossible with the instruments now in use. Bending or breaking of the lithotrite can scarcely occur if the instrument has been properly tested before being used. Jamming of the instrument by a hard fragment becoming wedged in the angle between the male and female blades where they join the shaft is practically impossible with the modern instruments. If it should happen, the bladder may be opened in the perinæum using the lithotrite as a staff, and the blades brought out and freed, or they may be exposed by suprapubic cystotomy, and cleared or cut off with a file according to circumstances.

Accidents after the Operation.—**Hæmorrhage** is a rare occurrence. Should the bladder become filled with clots they may easily be removed by reintroducing the evacuating catheter and sucking them out with the evacuator, or by the introduction of a large sized gum-elastic catheter, to which an aspirator may be applied.

Impaction of Angular Fragments of Stone in the Urethra.—This most dangerous and painful accident was not uncommon in the old system of lithotritry. In modern lithotritry it can happen only if a large fragment has been accidentally left behind or if from any cause the operation has to be left incomplete. If there is any reason to believe that fragments are left in the bladder the patient must be kept in a recumbent position, as impaction

most commonly arises from moving about too much or straining to pass water in an upright position. The lodgment of a fragment not only occasions great local irritation, ending perhaps in cystitis or abscess, but may give rise to severe rigors and nervous prostration. The fragments are especially apt to lodge in the prostatic urethra, or about the bulb. When the pieces are impacted low down in the urethra, it is absolutely

Fig. 892.—Urethral Lithotrite.

necessary to remove them from the canal as speedily as possible, lest the constitutional disturbance occasioned by them prove fatal to the patient. This may be done in various ways. Most frequently, they may be pushed back into the bladder, by passing a large catheter carefully down to them. The most convenient instrument for this purpose is one that is open-ended, so

Fig. 893.—Urethral Forceps.

that the fragment may be received in the aperture at the end of the instrument, and so pushed on before it. Through such a catheter as this a stream of water may be injected, and the fragment thus forced back. Should these manœuvres fail, it has been proposed to crush the fragments in the urethra with a small lithotrite (Fig. 892); but this plan is somewhat hazardous, as it

Fig. 894.—Urethral Forceps, with Alligator-jaw action. The smaller figure presents the Jaw of Forceps open.

is very difficult to avoid pinching up the mucous membrane of the canal with the bits of stone. The safest practice seems to be, either to extract them through the urethral orifice, or to cut them out through the perinæum. Extraction through the urethral orifice may be effected with forceps (Figs. 893, 894), or with Civiale's instrument (Fig. 318, Vol. I.). Should these means fail, or should the fragment be very deeply seated, as in the membranous portion of the urethra, and the local and constitutional irritation produced by

it be so great as to threaten abscess or a fatal termination, the better plan would be to remove it through a median incision in the perinæum. If such an operation as this be required, the Surgeon might feel disposed to extend the incision a little, and empty the bladder of any remaining detritus by means of a scoop.

Cystitis.—The occurrence of cystitis was formerly attributed solely to the mechanical irritation to which the bladder is subjected during the operation. The success which has attended lithotripsy at a single sitting has however demonstrated beyond a doubt that the bladder is much more tolerant of mechanical irritation than was at one time believed. The effect produced directly by the operation is, in most cases, limited to slight catarrhal inflammation, with an abundant secretion of mucus and some irritability of the bladder. In the operation by numerous sittings this was frequently aggravated by the presence of large and angular fragments. The thick mucus secreted under these circumstances is never perfectly expelled, but a certain amount remains adhering to the mucous membrane of the bladder after micturition. This speedily undergoes decomposition, and the most potent cause of cystitis is the contact of this foul mixture of mucus and urine within the interior of the bladder. When decomposition sets in, the alkaline products of the decomposing urine render the mucus thick and ropy, and this still further adds to the difficulty of its complete expulsion. Under these circumstances the patient becomes poisoned by the absorption of the putrid contents of the inflamed bladder, the temperature rises, the tongue becomes brown, and if not relieved the condition will very likely terminate in death, the immediate cause of the fatal result being, in most cases, extension of the decomposition to the pelvis of the kidney and suppurative nephritis. Such a condition necessarily offers an insuperable obstacle to any further crushing operation, supposing any stone to be still present, and the only course that gives a chance of life is to perform median cystotomy, by which not only are the fragments removed but the bladder is efficiently drained of its decomposing contents. The prevention of this complication is best accomplished by the use of antiseptics. The instruments should be oiled with carbolized oil and washed in carbolic lotion before being used, and the water used to wash out the bladder should contain some antiseptic. Decomposition may, however, reach the bladder along the partially stagnant layer of mucus which forms in the urethra as the result of catarrhal inflammation of the mucous membrane. It is not sufficient therefore merely to carbolize the instruments and to use antiseptic solutions in the evacuator; the end of the penis should be constantly covered with a strip of lint soaked in glycerine and carbolic acid. In spite of all precautions, however, decomposition sometimes takes place, and then the bladder must be washed out twice a day with an antiseptic solution. The mechanical irritation caused by so doing is of little importance when compared with the dangers of a septic accumulation in the bladder.

Atony of the Bladder is one of the most dangerous conditions that can occur in lithotripsy. This happens usually in old people, in whom the urinary organs may appear to be in a peculiarly favourable condition before the operation, the patient being able to hold his urine for six or eight hours, and to bear the injection of ten or twelve ounces of fluid. The danger of the condition is, that the bladder does not possess sufficient contractile power to expel

its contents. These consequently accumulate in the lower fundus, and irritate the mucous membrane; and thus the foundation may be laid for fatal septic cystitis. The atony of the bladder appears to arise partly from that natural want of expulsive power which is not unfrequent in old people, and partly from paralysis of the organ, induced by the contact of the instruments, especially after a prolonged operation. The bladder must be regularly emptied with a catheter, and antiseptic injections if there be any evidence of cystitis.

Disease of the Kidneys is in Lithotrity, as in all other operations on the urinary organs, the most common cause of danger and of death. The various forms of fatal kidney disease have been fully described in Chapter LXV.

Pyæmia and Septicæmia are occasional but uncommon causes of death.

Constitutional Disturbance.—Very considerable constitutional disturbance occasionally follows lithotrity. The patient is seized with severe and long-continued rigors, followed by profuse sweating, lasting for many hours. These serious symptoms were formerly most apt to come on after the first sitting; but the experience of Bigelow's method has shown that they are not more prone to occur after a prolonged operation than after the short sittings formerly adopted. They may pass off quickly, as in the analogous conditions to those that are apt to follow the introduction of instruments in stricture, &c., or they may persist and assume the character already described as indicating septicæmia or renal inflammation. These serious consequences are especially apt to happen when there is previous disease of the kidneys. Indeed, there is no condition that is more directly antagonistic to the success of lithotrity than interstitial nephritis. In other instances, again, the fatal result is more directly dependent on the irritation induced by the operation leading to the formation of abscesses in the neighbourhood of the prostate, or around the neck of the bladder; and in other instances, again, on the supervention of unhealthy suppuration in some of the sacculi that are occasionally met with in this organ. The *Treatment* of this state of things should consist in the free administration of stimulants—brandy, ammonia, and ether—followed by a full dose of opium, and abundant warm diluents. If the bladder contains foul urine this must be removed by washing out with antiseptic solutions. Especial care must be taken in those cases in which any stone remains not to repeat the sitting for at least a week or ten days after the rigors have passed off.

Mortality.—The rate of mortality following lithotrity in the adult, in the hands of a Surgeon especially skilled in the performance of the operation, is shown by the results recorded by Thompson in a paper read before the Royal Medical and Chirurgical Society in 1890. The record includes 800 operations performed upon 685 patients. Of these 475 were performed by multiple sittings, with 33 deaths, or 7 per cent.; whilst of 325 cases in which the modern operation at one sitting was performed only 12, or a little over 3½ per cent., died. This list does not include uric acid or oxalate of lime concretions of less than twenty grains in weight, nor the phosphatic concretions so frequently removed from the bladder of patients with enlarged prostate.

Barling has collected 300 cases of lithotrity performed in thirteen hospitals in this country during the years 1888 to 1892; of these 24 or 8 per cent. died. In 43 cases the patients were under 10 years of age; of these only one died.

LITHOTRITY IN BOYS.—Until Bigelow introduced his method, although lithotrity had occasionally been performed on boys, it was not considered a satisfactory or advisable proceeding, partly because of the small size and delicate structure of the child's urethra, and partly because of the difficulty of expelling the fragments. During the last few years, however, it has been extensively practised with the most satisfactory results, especially in India, by Keegan, Freyer, Dennis and others, and in this country by Walsham, Southam, Barling and others. Keegan has clearly shown that the urethra of a male child is much more capacious than is generally supposed. The smallest lithotrite used in any case was No. 4½, but in the great majority of children over three years of age, No. 8 could be passed with ease. The urethra should be measured before selecting the instrument, either by a urethrometer or a conical bougie. If necessary the meatus must be enlarged. Keegan finds that the narrowest part of a child's urethra, except the meatus, is at the junction of the penile and scrotal portions, 2½ to 3 inches from the meatus. The lithotrite must be fully fenestrated, so that the risk of the instrument becoming clogged may be as small as possible.

The size of the evacuators varies from No. 5 to No. 10; as a rule, No. 8 or No. 9 can easily be passed. The evacuating catheters must be provided with stylets, which should be introduced before the instrument is withdrawn, with the object of displacing any fragment which may be engaged in the eye of the catheter. The details of the operation are the same as in the adult, and all the manipulations must be carried out with the greatest gentleness. The bladder should be emptied and then injected with 2 or 3 ounces of warm boric lotion. Keegan lays it down as a rule that no instrument must be used which will not pass freely in and out of the bladder, and he states that he has met with cases in which no lithotrite could be safely used, and cutting became necessary. He states that small fragments are apt to remain at the neck of the bladder; these can be felt with a finger in the rectum and pushed back on to the floor of the bladder. The aspirator must be worked very gently.

The **special dangers** of lithotrity in young children depend on the small size of the parts in which the manipulations are carried out, and the ease with which, unless the greatest care be taken, the urethra may be lacerated or the bladder wall torn. Edmund Owen has recorded a case in which rupture of the bladder occurred during the use of the aspirator. The rupture, which was extraperitoneal, was sutured through a suprapubic incision, and drainage was established by a perinæal incision, but unfortunately the child died of collapse in eight hours.

The **Mortality** attending lithotrity in children in the hands of Surgeons skilled in the operation has been remarkably low. Thus of the first 125 cases recorded by Keegan only 4 died, the fatal result in each case being due to organic kidney disease. The ages of the children varied from one year and nine months to fourteen years, the average age being 6·38 years. The average weight of the stone was 89·15 grains, and the average stay in hospital was 4·5 days. In only one case was there known to be recurrence of the stone. Of a total of 663 lithotrities in children performed by eight Surgeons in India only 18 died, giving a mortality of 2·71 per cent.

tional cases, chiefly those in which the stone is very large or the introduction of the necessary instruments impracticable. At the present time it is possible to decide with certainty which plan of treatment will prove superior for general adoption. In the hands of a Surgeon skilled in the necessary manipulations it may justly be concluded that lithotrity for the stricture, and suprapubic lithotomy for exceptional cases, yield results equal, not exceeding, those obtained by any other line of treatment. When,

on the other hand, a Surgeon who has had but limited experience of lithotrity in the adult, is called upon to treat a case of stone in the bladder of a child, it will probably be wise to resort to lithotomy rather than to the crushing operation.

Concerning the choice between the lateral and the suprapubic operations in a case in which either is available, it may be said that no very reliable evidence can be obtained from statistics, which in the case of the high operation are derived largely from cases in which it was performed on account of the great size of the stone or other unfavourable conditions. No evidence is yet forthcoming to show that the suprapubic operation is attended with lower mortality than the lateral, when performed by practised hands. It must, however, be allowed that the suprapubic operation is the easier and requires no special manipulative skill or experience, and thus recommends itself to the general Surgeon, whose opportunities of operating for stone are limited, and who bears in mind the important fact that when a child dies after lateral lithotomy it is almost invariably as the result of some accident connected with the operation. In the treatment of large stones the high operation should certainly be preferred, as also when the case is complicated by deformity of the outlet of the pelvis or ankylosis of the hip. Lastly, the lateral operation is said, especially in children, to leave the patient sterile, from injury to the ejaculatory ducts; Haemstadth found that of eighteen married men in whom lateral lithotomy had been performed in childhood only one had children. The remarks which will subsequently be made regarding the influence of disease of the urinary organs in determining the choice of an operation in the adult have but little bearing in the case of children in whom the bladder and kidneys are rarely in a condition of advanced disease.

In **Adult Males** the general question may be considered by a reference to statistics, whilst in dealing with an individual case the Surgeon is guided in his choice chiefly by the size and character of the stone, and the condition of the urinary organs.

As Thompson pointed out in his admirable course of Lectures, delivered at the Royal College of Surgeons, the only method by which we can ascertain the effect of lithotrity in reducing the mortality from stone in the bladder, is to contrast the results obtained when lithotomy was the sole operation practised with those of the present day, when lithotrity has become the rule and the cutting operation the exception. For this purpose he contrasts the statistics of three periods: first, when lithotomy only was performed; secondly, the transitional period from 1835 to between 1860 and 1870, when about an equal number of cases were submitted to each operation; and lastly, the modern period, when lithotomy has been the exception. For the first period he selects the statistics of the Norwich Hospital from 1770 to 1830, as published by Crosse. During that period 326 adult males were cut for stone; of these 64 died -- 20 per cent. 75 cases were over 60 years of age; of these 22 died, or 29 per cent. These figures correspond very closely with the

larger statistics collected by Thompson, including 1,827 lithotomies. Of these 799 were adults, of whom 161 or 20·2 per cent. died.

For the second period Thompson gives the statistics of Keith of Aberdeen and Fergusson. Keith operated on 277 male adults, of whom 45 died, or 15 per cent. Of these 161 were cut, with 38 deaths or 24 per cent.; 116 were submitted to lithotrity, with 7 deaths or 6 per cent. Fergusson operated on 219 male adults, of whom 45 died or 20 per cent. Of these 110 were cut with 33 deaths, or 30 per cent.; 109 were crushed, with 12 deaths, or 11 per cent.

For the third period we may take Thompson's own recent statistics, giving the results of his practice between 1878 and 1889.

Of 434 male adults submitted to operation 32 or 7·3 per cent. died. Of these 378 were crushed (325 at one sitting), with 14 deaths, or rather over 3½ per cent. In 39 perineal lithotomy was performed, with 14 deaths, and in 17 suprapubic lithotomy was performed, with 4 deaths.

The general result of these figures is to show that when lithotomy was the mode of treatment, about 1 in 5 of all adult males operated on died. During the transition period the death-rate was about 1 in 6; since lithotrity has become the operation of choice, it has fallen to about 1 in 10.

It can hardly be decided that lithotrity should be the operation of choice for the treatment of a stone in the bladder of the adult male, in any case where there is no present or future condition which offers a definite contra-indication to its use. In this connexion we must consider the character of the stone and the condition of the urinary organs.

Size and Character of the Stone.—With regard to the size of the stone, it is generally held that a small stone is more favourable for lithotrity than a large one. A calculus below one inch in diameter may easily be crushed, but if any circumstance is present rendering the operation undesirable, it is more difficult to lay down a rule for larger stones. Formerly, it was not considered advisable to attempt to crush a stone that was above one inch and a half in diameter; but by the introduction of Bigelow's method, stones considerably above this size have been successfully removed. Much will depend on the composition and density of the calculus. The chief objection to lithotrity in large stones was not so much that the stone could not be broken, because unless it was too large to get into the blades of the lithotrite this usually could be done; but that the mass of fragments to come away by the urethra, and the repeated operations required for their removal generally caused a dangerous amount of hæmorrhage. The use of evacuators has overcome these objections for stones of any size in diameter; but we are not in a position as yet to say what is the largest stone that can safely be attacked. The different forms of stone vary considerably in the ease with which they are broken up. *Uric acid* calculi, giving a greenish or reddish colour, do not disintegrate readily, but split up into sharp and angular fragments. *Oxalate of lime* calculi, occurring chiefly in young people, break up very readily; and, as there is usually a co-existing healthy state of the urinary organs, the cases have a favourable issue. *Phosphatic* calculi, which are soft and friable, and do not yield angular fragments requiring evacuation, may, even if of larger size than that mentioned, be removed. At the same time the patient may often derive great benefit from

the thorough washing out of the bladder with the evacuator, as these concretions are commonly the result of chronic cystitis, with alkaline decomposition of the urine. But the shattered state of system, and the irritable condition of the urinary organs accompanying phosphatic calculi, often counterbalance the advantage that would otherwise have been derived from the character of the stone.

The presence of *several stones* does not add materially to the difficulties of lithotrity. If, however, the numbers are very large and the size small, it would perhaps be safer to remove them by lithotomy than by a prolonged crushing operation which might take one or two hours. Thus, in one case I removed 50 small calculi, varying from a quarter to half an inch in diameter, by the median operation. Occasionally multiple calculi are very small, so that they can mostly be washed out uncrushed through the evacuator; from 50 to 100 separate stones may be thus removed.

The rule may, therefore, at the present time, be summarised thus:—Any stone which can be grasped by the lithotrite and broken may be removed by lithotrity provided other conditions are favourable.

2. The Conditions of the Urinary Organs that influence the propriety of performing lithotrity or lithotomy have reference to the state of the *kidneys*, the *bladder*, the *urethra*, and the *prostate*.

The question of the advisability of lithotrity was, before Bigelow's improvements in the operation, much influenced by the degree of irritability of the bladder and urethra, and the ease with which the patient bore the introduction of instruments, but these points have little influence now that the operation is done at one sitting under an anæsthetic. In fact an irritable patient would suffer far less from lithotrity than from lithotomy.

Cystitis, if moderate in degree, is no bar to lithotrity at one sitting unless the stone be very large; in fact the removal of the calculus and the thorough cleaning of the bladder by the evacuator frequently leads to rapid improvement. If, however, the stone is large, the cystitis severe, the irritability of the bladder great, and more especially if the patient be old and the inflammation has not yielded to the ordinary treatment, lithotomy will probably be the safer proceeding. Great hypertrophy of the bladder with fasciculation and sacculation are disadvantageous for lithotrity owing to the difficulty of completely removing the fragments with the evacuator. Still by thorough washing and by repeating it, perhaps in a few days, the difficulties may be overcome. The difficulties in lithotrity from atony of the bladder have already been described (p. 1091). At the present time atony of the bladder is no objection to lithotrity. Stricture of the urethra under ordinary circumstances offers no great obstruction to lithotrity (p. 1089). In fact, if a staff can be passed on which lithotomy could safely be performed, the stricture can easily be stretched up to the point necessary to admit the lithotrite and the evacuating catheters. Enlargement of the prostate, unless very excessive, offers but little difficulty in lithotrity (p. 1088). Acute inflammatory disease, or abscess of the prostate, necessarily prevents the performance of lithotrity.

In encysted calculus lithotrity is obviously impossible.

The condition of the *kidneys* merits special attention. If these organs be the seat of consecutive nephritis (p. 1001), the danger of any prolonged operation in the bladder is greatly increased. If, therefore, the stone be a large one, and especially if cystitis also be present, lithotomy is probably the safer opera-

tion. If, however, the stone be of only moderate size it may more safely be crushed. In lithotripsy the danger of renal disease consists chiefly in interference with the function of the kidneys following a prolonged operation: in lithotomy this danger is less in proportion as the operation is shorter, but there is an additional source of danger in the tendency to diffuse inflammation of the bladder and surrounding tissue that always coexists with kidney disease.

Diabetes is not commonly associated with calculus. I have, indeed, but very rarely seen the two conditions combined. The only form of calculus that I have seen in diabetic patients has been the uric acid. It is necessarily very hazardous to operate in such cases, at least by lithotomy. And even if lithotripsy be determined on, it would be well to defer the operation until the glycosuria has been checked or removed, at least for a time, by proper treatment.

I have said nothing in this comparison between cutting and crushing of the comparative painfulness of the two operations, as both are in the present day done during anæsthesia. The suffering during the after-treatment, when all goes well, is about equal, while the discomfort is infinitely less in lithotripsy.

To sum up, therefore, the rules of practice may be given as follows:—

In all ordinary cases in the adult, lithotripsy by Bigelow's method at a single sitting should be the rule of practice for stones up to two inches, provided they are not too hard to be crushed by the lithotrite.

When the stone is above two inches in diameter, or when a large number of small stones are present, lithotomy is usually preferable.

Lithotomy is required in cases of extreme enlargement of the prostate, encysted calculus, or large stone with severe cystitis.

As a general rule the *suprapubic* operation should be selected in those cases in which lithotripsy is contraindicated or impracticable. When the cutting operation is resorted to on account of the size of the stone, suprapubic lithotomy should always be performed. The same may be said of encysted calculus (p. 1038), and great enlargement of the prostate; in the latter case the Surgeon may thus be enabled to deal with the prostatic outgrowth as well as to remove the calculus (*see* Hypertrophy of Prostate). When lithotomy is performed because of very severe cystitis the *median* operation may be undertaken if the stone is small, but suprapubic drainage has proved so satisfactory that this condition also may be treated by the high operation.

The Result of Operations for Stone will depend in a great measure upon the condition of the bladder, and the character of the stone. If the bladder be healthy, all symptoms will cease on the removal of the calculus, and the patient will be restored to perfect health. This usually happens when the calculus is of the uric acid or the oxalate of lime variety, and of renal origin. If, however, the bladder be unsound, irritable, and the urine alkaline from decomposition, and disposed to the deposit of phosphatic matters, the calculus being phosphatic, and chiefly, if not wholly, vesical in its origin, then an irritable state of bladder may be left, or may speedily return after the operation, which will consequently have been productive of little, or only of temporary benefit.

Recurrence of Calculus after Operation.—This may take place from four distinct causes:—1, in consequence of a continuance of the constitutional condition, under the influence of which the calculus was originally formed: 2, from the descent of a renal calculus, which has existed in the kidney before

the first operation ; 3, from a fragment of calculus having been accidentally left in the bladder ; and 4, from the accumulation of phosphatic deposit in the fundus of the bladder, or in the line of imperfectly healed incisions.

Relapse from the first cause is probably not very common. When it occurs, the recurrent calculus is of course of the same composition as the primary one. The occasional occurrence of relapse shows the necessity of continuing constitutional treatment adapted to the particular diathesis, after the removal of the calculus from the bladder.

Recurrence of calculus from the descent of a new stone from the kidney is especially liable to be met with in those cases in which the primary calculi are multiple and small. In these cases, the relapse may take place very shortly after the first operation, and will be preceded by the usual symptoms of the descent of a stone from the kidney.

Relapse from the retention of a fragment which serves as the nucleus of another stone, will undoubtedly occasionally occur, although its occurrence is fairly attributable to want of due care on the part of the Surgeon. It is apt to happen more frequently after lithotrity than after lithotomy, and it is probably to this cause chiefly that we must refer the greater liability to relapse after the crushing than the cutting operation. But it may happen after lithotomy that a fragment is left behind when the stone has been broken, during extraction, and the bladder not thoroughly washed out. But even in this case, the bit of stone will usually be carried out of the wound by the flow of urine through it.

Recurrence from the formation of a phosphatic calculus in the bladder, as the result of chronic cystitis with decomposition of the urine, may occur occasionally after lithotomy, but is much more common after lithotrity. In these cases a lithotrite must be passed, and the soft mass crushed up and washed out with a catheter and evacuator. The patient must be taught to wash his own bladder out regularly every day with a dilute acid solution, to which some quinine may be added. I once had under my care a patient eighty years of age, on whom I performed lithotrity for a uric acid calculus. During the next five years I removed large phosphatic concretions on more than a dozen occasions. At last the tendency to recurrence ceased, and for three years before his death no new formation took place. On some occasions the mass measured over an inch and a half in diameter, yet under anæsthetics it was broken up and washed out with Bigelow's apparatus without the slightest irritation, the patient usually returning to the country on the second day after the operation.

Phosphatic deposit may take place also in the track of a partially healed lithotomy wound, forming a crust on its surface. I have known such a deposit to form in the perinæum, when the wound had degenerated into a sinus.

According to C. Williams, the relapses in the Norwich Hospital were 27 in 1015 operations, or 1 in 36, or in 935 lithotomies 1 in 33. Lithotomy was performed a second time on 24 patients; a third time on 3; and a fourth time on 1. Twenty-three were cured, 5 died. All the patients were males. The registers of the Louisville Hospital give 1 relapse in 116 cases of lithotomy ; and according to Civiale the return of calculus after lithotomy was in Bavaria 1 in 32, in Bohemia 1 in 46, in Dalmatia 1 in 43, and in France 1 in 74.

After lithotrity, relapse is more common ; although it is probably less

frequent now than formerly, and will become less frequent as the details of the operation come to be better understood and more carefully practised. In the practice of Civiale it occurred about once in every tenth case. It still occurs often enough to show the necessity of the Surgeon most carefully examining the bladder before he pronounces the patient cured; and even then watching him for some length of time, in order to meet a recurrent calculus at its first formation, and to adopt means for its early removal. Lithotrity cannot therefore be said to be so complete a cure in all cases as lithotomy.

Not only is recurrence of calculus more common after the former than after the latter operation, but it occasionally happens that patients who have been lithotritized successfully, and in whom no recurrent calculus has formed, continue to suffer for a great length of time afterwards from very distressing irritability of the bladder, which resists in the most obstinate manner all the ordinary methods of treatment. This is not the case after lithotomy; when a patient once recovers his bladder usually regains its tone completely, and no trace of evil consequences is left.

Treatment.—In the event of a secondary calculus forming, whether after lithotomy or lithotrity, either method may again be employed, according to the nature of the case. As a rule, the bladder may be cleared of the recurrent calculus by means of the lithotrite. If lithotomy be performed, the suprapubic method is probably the best, even though the primary stone had been removed from the perinæum. The scarring and altered relations of the parts would probably render a repetition of the perinæal operation difficult, and if the rectum have become adherent to the membranous portion of the urethra and the apex of the prostate, in consequence of the contraction of the old cicatrix, the danger of wounding the bowel would be considerable.

URETHRAL CALCULUS.

Calculi are not unfrequently found impacted in the urethra, especially in boys. They are most commonly formed in the kidney, whence they pass into the bladder, and thence into the urethra, through which they usually escape; but in some instances they lodge in the latter channel, more especially at the bulb or in the navicular fossa. These calculi are commonly of the uric acid or oxalate of lime varieties; they are generally round, but not uncommonly elongated or spindle-shaped.

There can be little doubt, however, that in some more rare cases calculi may be formed primarily in the urethra. They will then be found to be phosphatic, usually consequent upon stricture, and perhaps of large size. In some cases these concretions are moulded in the prostatic and bulbous portions of the urethra, being elongated, rounded at one end, and pointed at the other. In other instances, again, they appear to be formed in a pouch that lies to the outside of the urethra, and is connected with it only by a small aperture. I have removed a stone of this kind composed of triple phosphate, weighing an ounce, and about the size of a walnut, smooth and rounded, from a point lying between the upper wall of the urethra and the symphysis pubis, in a clergyman who had for many years suffered from very tight stricture. One of the most remarkable instances of this kind is represented in Fig. 895, taken from a drawing in Carswell's collection at University College. The stone here was of very large size—equal in bulk to two horse-chestnuts.

Impaction of a Calculus in the Urethra of an Adult may be suspected by the difficulty that is occasioned in micturition, and ascertained by the possibility of feeling the stone through the walls of the canal, or of detecting it by introducing a sound into the urethra.

Treatment.—In the adult, urethral calculi may be removed by extraction, lithotrixy, or incision. When situated towards the anterior part of the canal, a urethral calculus may frequently be extracted by working it forwards between the finger and thumb, the patient being under chloroform. Should this plan not succeed, it may be removed with a long and very narrow-bladed pair of forceps; occasionally, when it has reached the navicular fossa, it will not pass through the meatus unless this be enlarged with a probe-pointed bistoury. If the calculus cannot be extracted in this way, it should, if possible, be pushed back into the bladder and removed by lithotrixy. If, however, it be firmly fixed, an incision must be made down upon it, through the urethra, by which it may be removed. It is a good rule not to make this incision in any part of the urethra anterior to the scrotum if it is possible to avoid it; for, in consequence of the coverings of the penile portion of the urethra being very thin, the aperture will probably not close, but a fistula will be left. When the stone is situated in the scrotal portion of the urethra, there would be some risk of abscess and of urinary infiltration if the incision were made through the lax tissues of the scrotum. Hence if, as it sometimes happens, the stone may be pushed back to the bulb or membranous urethra, but not into the bladder without using a dangerous amount of force, it is better to cut down upon it, and extract it through the perineum by an incision in the mesial line. This operation may readily be done by passing a staff, grooved along its convexity, or an ordinary director, as far as the calculus, and making an incision upon the end of it, so as to lay open the urethra; the staff is then removed, and the calculus extracted by means of a slender pair of forceps. A catheter should next be passed into the bladder, and retained there for a few days, in order to lessen the tendency to the formation of urinary fistula.

It may happen that the calculus, impacted in the urethra, is only one of several; others being lodged in the bladder. After removing the calculus from the urethra, the Surgeon should pass a sound into the bladder, so as to ascertain whether any other concretions exist in that organ; and if so, they should at once be removed by the median operation of lithotomy, the incision in the membranous portion of the urethra being extended backwards to the prostate. I once saw Liston extract two vesical calculi, after having removed one that had blocked up the urethra, by converting the perineal incision into that of lateral lithotomy.

Impaction of a Calculus in the Urethra of a Boy.—In boys the impaction of a calculus in the urethra is almost the sole cause of retention of urine. When called, therefore, to a child suffering from this condition, we should always examine the urethra from the perineum or rectum, and

Fig. 805.—Extra-urethral Calculus.

by the introduction of a sound. Relief may be given in one of two ways: 1. If the stone be near the meatus, it may be extracted; and, 2, if situated more deeply, it may be pushed back to the perinæum, there fixed by the finger, and cut down upon in the mesial line. It should not be pushed back into the bladder unless the Surgeon is prepared to crush it; and as in children this operation requires special instruments, it can only be exceptionally that such a line of treatment would be justifiable.

If the stone is allowed to continue fixed in the urethra very serious consequences may ensue. If it completely obstructs the canal, the membranous part of the urethra may give way during the violent efforts at micturition, and extravasation of urine will take place. In other cases, if it be irregular in shape, a small quantity of water may pass. Under these circumstances there is intense irritability of the bladder, the urine passing with much pain every few minutes, or constant dribbling may set in. The distended bladder can be recognized above the pubes. The penis is usually turgid and semi-erect. Some purulent discharge will be observed about the meatus, and there will be some hard ill-defined swelling in the perinæum, with much tenderness in this region. The presence of the stone may at last cause ulceration of the urethra with the formation of urinary abscess in the perinæum, followed perhaps by extravasation of urine into the scrotum and its diffusion beneath the superficial fascia in the usual direction, with the ordinary disastrous results of inflammation and sloughing. On passing a sound, no stone probably will be found, as this has escaped from the urethra, and is lying in a pouch in some part of the perinæum, and in the midst of the broken-down areolar tissue and pus; into this cavity the sound will readily pass.

The *Treatment* in these cases is simple. It consists in introducing a grooved staff, placing the boy in the lithotomy position, and then freely incising the mesial line of the perinæum, so as to open up the urinary abscess; in this the stone may be found, or it may be so enveloped in the sloughy tissues as to escape detection; perhaps it will escape through the wound in a few days, and be found lying in the bed. Should there be much hæmorrhage a catheter may be tied in and the wound plugged with salicylic or iodoform-wool secured by a T-bandage. If extravasation of urine have occurred, free incisions must be made in the usual way, and the child be put upon a stimulating diet.

For **Foreign Bodies in the Bladder**, see Vol. I., p. 895.

CALCULUS IN THE FEMALE.

Stone is of rare occurrence in women; in London, certainly, it is not often met with. Thus, South states that, during a period of twenty-three years, 144 males were operated on for stone at St. Thomas's Hospital, and only 2 females. In some districts, however, stone would appear to be more common in women than this. Thus, according to Crosse, at the Norwich Hospital, the proportion has been about 1 woman to 19 men. Civiale stated, as the result of his researches, that in the North of Italy, the proportion was 1 to 18; and in France, about 1 to 22. At University College Hospital we had not had a case of stone in the female for many years until 1855, when three came under my care in the course of a few months; and since that period many have occurred.

Vesical calculi in the female are often nothing more than phosphatic incrustations deposited around some foreign body that has, either accidentally or from depraved motives, been passed up the urethra. In this way hair-pins, pieces of bougie, of catheter, or of pencil, will often be found to form the nucleus of the concretion.

The **Symptoms** of stone in the female closely resemble those that occur in the male, and its presence may usually be easily detected by means of a short and nearly straight sound, or a female catheter. It is often simulated very closely by the irritation occasioned by a vascular urethral caruncle, or by an irritable bladder. The larger calculi can be felt from the vagina if firm pressure be made at the same time above the pubes.

Large calculi may be met with in very young female children. I have removed a uric acid calculus encrusted with phosphates, measuring $1\frac{1}{4}$ inch in length by $\frac{3}{4}$ inch in breadth, from a little girl four years old. The stone was removed unbroken, by gradual dilatation of the urethra. In the adult they may attain a very large size. I have extracted one measuring 8 inches in its long, and 6 inches in its short circumference from a young woman.

Calculus in the female bladder, if allowed to remain unrelieved, will occasion the same morbid conditions in the urinary organs as occur in the male. The stone may be discharged spontaneously through the urethra—if of small size, without any bad results following; but if large, by a process of ulceration, in consequence of which permanent incontinence of urine will remain. It may slough through into the vagina; or lastly, it may offer a serious obstacle during parturition to the descent of the foetal head, when, if it cannot be pushed aside to be dealt with afterwards, it must be cut out, or craniotomy must be performed.

Treatment.—A stone may be extracted from the female bladder by one of three methods: 1, by Dilatation of the Urethra; 2, by Lithotrity; 3, by Lithotomy. These different operations cannot be employed indiscriminately, but each one is more especially adapted to certain kinds of calculus.

1. **Dilatation of the Urethra** is the simplest method and is available for the removal of small stones. The dilatation may best be performed with Hegar's uterine dilators. In this way the canal can, in the adult, easily be dilated sufficiently to allow the introduction of the index finger and the extraction with forceps of a stone eight or ten lines in diameter, without any evil results. In the removal of moderate-sized calculi, however, the great objection to the operation is the liability to incontinence of urine resulting from it. This is not by any means necessarily complete; but a weakened state of the bladder results, so that the patient cannot hold her urine for more than an hour or two at the most.

2. **Lithotrity** should as a general rule be practised in cases in which the stone is of moderate size, but too large to be removed whole through the dilated urethra. The operation requires to be practised on the same principles as in the male, but differs in certain details. The chief obstacle consists in the difficulty with which the bladder retains urine or water that is injected into it. In consequence of this there may not only be great difficulty in seizing the stone, the bladder collapsing and falling into folds around it, but also danger of injuring the mucous membrane with the lithotrite. In order to cause the bladder to retain the necessary quantity of urine, the pelvis must be well tilted up, and the urethra compressed against the lithotrite by the

fingers of an assistant. It is well not to dilate the urethra before the introduction of the instrument, as this difficulty is thereby increased.

The ordinary male lithotrite is not a very convenient instrument to use in the female bladder, the handle being awkwardly long. This is especially the case in female children. Hence I have found it convenient to have a shorter instrument constructed, with which it is far more easy to work in the female bladder. The stone should be completely pulverized, as in the male, and the fragments removed in the same way with an evacuator and large catheter. This plan is much better than that sometimes recommended of dilating the urethra and extracting the pieces with forceps, as in this proceeding the sharp fragments are very likely to lacerate the mucous membrane. The whole stone must be removed at one sitting.

For all calculi in the female bladder, except those of the very largest size, this operation is the most applicable. I have in this way crushed and extracted at one sitting, from the bladder of a lady about 50 years of age, a phosphatic calculus fully as large as a hen's egg. Lithotripsy may be had recourse to at all ages, in the very young as well as the old. I have crushed and successfully removed a large calculus from a child three and a half years of age, the youngest patient on whom I have operated by this method. Although the urethra of so young a female child cannot, without danger of incontinence, be much dilated, yet it may safely and easily be enlarged sufficiently to admit a moderate-sized lithotrite.

3. **Lithotomy** should as a general rule be reserved for cases in which the calculus is of large size, or has formed around a foreign body, or in which very severe cystitis exists. The bladder may be opened above the pubes or through the anterior vaginal wall. The former operation is to be preferred, especially if, as is usually the case, the stone is large, or if cystitis is present. The vaginal operation is very easy, but is open to the objection of possibly leaving a permanent urinary fistula—a danger, however, which is probably not great if the lips of the incision have not been bruised by the forceps or by the extraction of the stone.

Suprapubic Lithotomy in women differs in no very material respect from the same procedure in men; except that it requires additional care in consequence of the difficulty there is in causing the female bladder to retain enough urine or water to make the viscus rise sufficiently above the pubes. The extraction of the stone is easy, as it can be raised into the grasp of the forceps by being pushed up from the vagina.

Vaginal Lithotomy is performed as follows: A short straight grooved staff is passed into the bladder and pressed downwards against the vesico-vaginal septum. A scalpel is then pushed through the anterior wall of the vagina and inferior fundus of the bladder into the groove in the staff, which it is made to enter just behind the neck of the bladder. The incision is continued backwards for $1\frac{1}{2}$ inch, and through the opening the forceps is passed and the stone extracted. Unless there be severe cystitis the incision may be closed with silver wire sutures, after thoroughly washing out the bladder with boric acid lotion.

Vaginal lithotomy may, in some cases, be the only alternative. I extracted, by this operation, a calculus measuring eight inches by six in circumference, from the bladder of a woman twenty-three years of age, who had suffered from symptoms of stone from childhood. The stone by its size offered so serious an

obstacle to the descent of the foetal head during parturition, that craniotomy had been rendered necessary ; the anterior vaginal wall had been a good deal bruised, and I feared that sloughing of it might take place ; hence I extracted the stone by the vaginal method.

Lithotomy is not so dangerous an operation in the female as in the male ; yet death occasionally occurs, especially in feeble children, from cystitis and peritonitis, more particularly if the extraction of the stone have been tedious and difficult, the bladder being much manipulated.

CHAPTER LXIX.

DISEASES OF THE BLADDER.

CONGENITAL MALFORMATION.

Extroversion of the Bladder, consisting in an absence of the anterior wall of the organ, with deficiency in the corresponding part of the abdominal parietes, is a congenital malformation occasionally met with. It may occur in either sex, but is more common in males.

This condition consists in an arrest of development, in consequence of which the anterior part of the pelvic girdle is deficient, the bodies of the pubic bones being imperfectly developed and the symphysis absent. The recti muscles separate at their lowest part, and pass obliquely outwards to be inserted into the lateral abutments of the pubic bones. A triangular space is thus left, which is filled up by the posterior wall of the bladder, which is continuous with the common integuments, the anterior wall being absent. The cleft commonly extends up to the spot at which the umbilical cord enters, so that the umbilicus is wanting. The posterior wall of the bladder, being pushed forwards by the pressure of the abdominal viscera behind, forms a prominent mass, the surface of which is composed of red, vascular mucous membrane; at its lowest part the orifices of the ureters will be seen discharging urine in constant drops. For a full description of the mechanism of the passage of the urine in this malformation, I would refer to a case which fell under my notice, and in which I made a number of experiments on the rapidity of the passage of foreign matters through the kidneys; it is reported in the *Medical Gazette* of 1845.

The penis is cleft along its dorsal aspect, exposing the floor of the urethra, forming the condition known as epispadias.

The scrotum is imperfectly developed, and the testicles usually do not enter it, but remain in the inguinal canals or just outside the external abdominal rings.

This malformation is of a most distressing kind. The exposed mucous membrane of the bladder becomes inflamed and irritated, and the constant soaking of the clothes with decomposing urine renders the patient an annoyance to himself and to all around him. Death may result from extension of inflammation up the ureters to the kidneys.

Treatment.—Up to a comparatively recent period the only treatment for ectopia vesicæ consisted in the application of a properly constructed instrument to collect the urine. A hollow shield is strapped over the part, and is connected by means of a tube with an india-rubber bottle, which is attached along the inside of the thigh. Of late years, however, operations have been devised and practised with the view of covering in the exposed surface of the bladder, so as to prevent the pain and irritation arising from contact of the clothes with it, and, by giving a proper conduit to the urine, to which an

apparatus can be applied, to save the patient all the annoyance of constant dribbling.

The first operation for the remedy of this malformation that was successfully performed was done, in 1859, by Ayres of New York, in the case of a woman aged 28. The operation consisted in turning down a long flap of skin from the abdominal wall above the exposed bladder, so that the cuticular surface of the flap was next the exposed mucous membrane. Lateral flaps were then dissected up from the abdominal wall on either side, and by sliding these inwards and uniting them with sutures in the middle line the raw surface of the first flap was completely covered. Three weeks later a covering for the vulva was fashioned by dissecting up the integuments covering the pubic bones on each side, and uniting them to each other in the middle line and to the lower border of the reversed flap.

Ayres was soon followed by Pancoast of Philadelphia, and subsequently by Holmes and Wood of London. The principle of their operations is essentially the same as that practised by Ayres, viz., that of raising flaps from the abdominal wall, and covering in the bladder by turning the cuticular surface of these flaps towards it. But the details of the operations differ chiefly in this, that the flaps have been taken from the groins and lateral aspects of the abdominal wall, with their bases downwards, so that they might be nourished by the superficial branches of the femoral artery.

Wood's Operation.—A flap composed of the skin and areolar tissue of the abdominal walls above the extroverted bladder is first dissected up. This flap is somewhat square in shape; its base should correspond in width with the exposed mucous membrane. Its length should be sufficient to cover the whole of the latter. The flap is turned down with its skin-surface towards the bladder. Then a "pyriform flap," the base of which is about equal in width to the length of the "umbilical flap," is dissected up from each groin, the base of the flap being "directed towards the scrotum and thigh" (Fig. 896). These two flaps are brought together so as to meet in the median line, and to cover in the umbilical flap, the raw surfaces of the two groin-flaps being in contact with the raw surface of the reversed umbilical flap. The flaps are then secured in position by hare-lip pins, each pin being passed so as to transfix both the groin flaps and a fold of the umbilical flap beneath, holding the three firmly together (Fig. 897). No sutures are required in the flaps. The edges of the wounds left in the places from which the flaps have been raised are then brought together by hare-lip pins and wire sutures (Fig. 897), and broad strips of strapping placed across so as to support the flaps and to remove as far as possible any tension from them. The patient must be kept in bed in a sitting posture, with the knees drawn up.

If the operation be successful, all the pins and sutures may be removed by about the sixth or eighth day, and cicatrization will probably be complete before the end of a month; the exposed surface of the bladder being completely covered in, leaving only a small opening about the root of the fissured penis, to which an apparatus may readily be adapted to catch the urine. If the umbilical flap be not of sufficient length, very troublesome fistulæ are apt to be left at its angles, requiring further plastic operations for their cure. Experience has shown that, if the operation be left at this stage, the benefit is not permanent. The contraction of the cicatrices, and the constant tendency to protrusion of the mucous membrane of the bladder from beneath the new

covering at the opening left at the root of the penis (Fig. 896), lead to a gradual increase in the size of the opening and a partial return of the symptoms. To prevent this, the fissured penis may be covered in by the following method. The whole front of the scrotum, including the dartos, is raised so as to form a bridge of skin connected with the groin at each side. This is lifted over the penis, and placed upon a raw surface prepared by turning down a collar or flap from the lower arched border of the new bladder-covering and from the sides of the urethra and penis as far forwards as the glans. A continuous wire suture is applied to keep the flaps in place; and the transplanted scrotal

Fig. 898.

Wood's Operation by Lateral Reversed Flaps. (After Wood.)

Fig. 899.

structures are united to the border of the bladder-covering by a line of interrupted sutures. The scrotal wound is readily closed by wire sutures. By this means a sort of urethra is formed, containing the muscular tissue of the dartos in its roof, which may even give it a slight power of contraction, so as to enable the new bladder to contain small quantities of urine. The second stage of the operation is often somewhat interfered with by erections of the penis. These are best controlled by ice-bags. The knees should be drawn up so as to relieve tension, especially in the first stage of the operation. After the cure is complete, the patient is often troubled by the growth of hair from the under surface of the umbilical flap, and the accumulation of phosphates

upon the hairs and in the angles of the new bladder. This is best relieved by extracting the hairs with a pair of forceps, and by using weak acid injections to remove the accumulation of phosphates.

Other methods have been devised in which the flaps by which the exposed bladder is covered are so disposed that the subcutaneous surface is directed backwards towards the vesical mucous membrane. This plan has been successfully adopted by Thiersch, who covers in the upper and lower halves of the exposed bladder in separate stages by the use of two large lateral flaps. The flap for the lower half of the bladder is raised by vertical incisions, but both ends are left undivided until the deep surface of the flap has granulated, when the upper attachment of the broad bridge of skin is cut across and the flap is turned across the lower part of the bladder, and adjusted with sutures to the freshened edges. Subsequently a similar strip of skin is raised from the abdominal wall on the other side of the bladder but at a higher level, and after granulation is well established, it is separated at its upper end and adjusted across the upper part of the bladder. The operation is completed by freshening the contiguous edges of the two flaps and uniting them with sutures, similarly uniting the upper border of the superior flap and the margin of skin at the upper border of the bladder, and treating the epispadias by the method described at p. 1217. In all operations in which granulating flaps are used, great care must be taken to cut them of sufficient size to allow for considerable shrinkage.

W. Anderson has successfully modified Thiersch's operation in two important respects. He first dissected away the upper half of the vesical mucous membrane and covered in the resulting raw surface by two lateral flaps united to each other in the middle line by sutures. Subsequently the remaining lower part of the exposed bladder was covered by two lateral flaps raised chiefly from the front of the thighs, and allowed to cicatrize thoroughly on their deep surface before they were adjusted in position.

The only other method which needs special mention is that which has been suggested and practised by Trendelenburg of Bonn, and was first performed in this country by Makins. **Trendelenburg's Operation** has for its object the approximation of the separated pubic bones whereby the subsequent closure of the defect is facilitated, and this object is accomplished by a free division of the ligamentous structures of the sacro-iliac articulation on each side. The operation is performed as follows: The child is turned on to its face, and each sacro-iliac joint is opened by a vertical incision over it, freely dividing the posterior ligament. Trendelenburg states that the left index finger introduced into the rectum will help to indicate the position of the incisions.

By firm pressure on the sides of the pelvis it is now possible to bring the separated pubic bones nearly or quite into contact. The incisions are sutured, drained, and dressed antiseptically, every care being taken to prevent their becoming subsequently soiled by the urine. The approximation of the two halves of the pelvis is maintained by a pelvic girdle, the ends of which are split and crossed in front and attached to weights hanging over the sides of the cot. The second part of the operation is performed after an interval of a month or six weeks. The exposed bladder, which is considerably narrowed and depressed as the result of the previous operation, is covered by making an incision on each side at the junction of skin and mucous membrane, and continuing each upwards to meet at a point above

the bladder. The skin is dissected up for a short distance around, and the edges are drawn across the bladder and united with sutures in the middle line. Trendelenburg and Thiersch have obtained satisfactory results by this method; in Makins's case the second part of the operation was followed by sloughing, but in the end a fairly satisfactory result was obtained by the use of flaps. The operation does not appear to have been followed by any weakening of the pelvis or interference with the walking power, and it certainly seems worthy of further trial in these distressing cases. It is available only in young children.

THE USE OF THE CYSTOSCOPE.

Before proceeding to consider the more important affections of the urinary bladder, it will be convenient to describe briefly the method employed in the examination of the interior of the bladder by means of electric illumination. This method of examination was first carried out by Nitze of Berlin in 1879, and since then its practical utility has been demonstrated, amongst others, by Hurry Fenwick in this country and by Meyer in New York.

The **Cystoscope**, in the improved form constructed by Leiter of Vienna, has the form of a hollow sound, with a short angular beak. The latter contains the electric lamp, which is exposed through a small window closed by a pane of rock-crystal. The rays of light from the illuminated object enter a window in the angle formed by the beak and stem of the instrument; they are here refracted by a prism, and, after passing through a series of lenses in the hollow stem, by which the size of the object is magnified, they enter the observer's eye, which is applied to the expanded ocular end of the instrument. For ordinary purposes the light and window are placed in the concavity of the instrument, but for examining the lower part of the bladder an instrument having the light and window on the convexity may be more convenient.

The bladder having been washed out and injected with at least four ounces of clear fluid, the cystoscope is passed in the same way as an ordinary sound. In health the mucous membrane of the bladder looks "very like the retina as seen through the ophthalmoscope."

The chief use of the cystoscope is as a means of examination in obscure urinary cases in which all other methods have failed to detect the nature of the disease. By its use the necessity of an exploratory operation may be avoided. It has been found of the greatest value in certain cases of painless hæmaturia, in which the vesical or renal origin of the blood has been doubtful. Among the conditions in which it may enable the Surgeon to make a diagnosis are certain forms of ulceration of the bladder; calculi which have not been detected with the sound in consequence of their being encysted, hidden in a pouch behind the prostate, or between folds of mucous membrane; tumours of the bladder; enlargements of the prostate; and suspected presence of a foreign body. Blood has been observed escaping from one ureter, and by observing the condition of the ureteral orifice, and the character of the jets of urine escaping from it, information has in some cases been gained as to the condition of the corresponding kidney.

The view of the bladder may quickly be obscured if the fluid in it becomes turbid or blood-stained.

There can be no doubt that cystoscopic examination is valuable as a last resource in many obscure cases. The passage of the instrument, followed, perhaps, by a somewhat prolonged investigation, must not be regarded as altogether free from danger, especially in the presence of renal disease. Damage to the mucous membrane by the heated beak of the instrument is an avoidable accident.

Considerable practice is required before the Surgeon acquires sufficient skill in the use of the instrument to enable him to feel confident of what he sees and to plan his subsequent treatment accordingly.

For the visual examination of the interior of the female bladder the simple cystoscope devised by Kelly of Baltimore will be found useful. It consists of a silver-plated cylindrical speculum, the ocular end of which is expanded and provided with a handle. For the first examination at least an anæsthetic should be administered, and as a rule the patient may be placed on the back, with the pelvis well raised. The urethra is dilated with Hegar's uterine dilators, and the cystoscope, fitted with a bullet-ended stylet, is introduced. For purposes of illumination direct sunlight is the most satisfactory.

With this instrument ulcers and other morbid conditions can be seen, and even treated. The orifices of the ureters may readily be examined, and special ureteral catheters may be introduced into them.

CYSTITIS.

ACUTE CYSTITIS is of frequent occurrence, and arises from many different causes. In many instances it is met with merely as a complication of some serious disease of the bladder, such as calculus or tumour.

Causes.—Acute cystitis may result from various forms of *injury*, such as occur during operations on the bladder or during parturition, or from the irritation caused by fragments of a broken calculus or by other foreign bodies lodged in its interior. The best example of cystitis resulting from the presence of a *chemical irritant* in the urine is that following the external or internal administration of cantharides. A mild form is described as being sometimes produced by partaking to excess of sour wine or new beer. To the same category probably belong at least some of the cases in which mild symptoms of cystitis occur in children who habitually pass urine which is highly acid or loaded with phosphates.

Septic cystitis includes a large proportion of the cases of acute inflammation of the bladder which are met with in practice. It results from simple putrefactive changes occurring in the bladder as a consequence of the introduction of septic micro-organisms from without. As predisposing causes of septic cystitis the presence of retained urine in the bladder and chronic congestion or inflammation of the mucous membrane are most important. The introduction of septic matter is most commonly brought about by the use of an imperfectly cleaned catheter; but independently of this it seems probable that infection may occur along the urethral canal, especially when the latter is imperfectly closed and filled with adherent mucus. Such conditions are doubtless sometimes present, more particularly when the bladder is completely paralysed as the result of injury of the spinal cord. In the female the entrance of septic matter along the short urethral canal is the most probable explanation of the frequency of cystitis without obvious cause in that sex.

In rare instances severe cystitis results from the introduction of a septic abscess into the viscous; such a case is occasionally met with in the female as the result of a pelvic abscess or pyo-salpinx. A severe form of septic cystitis may occur in females as a complication of retention of the urine. It is due to retention of urine, with dribbling from the over-full bladder; it may end in sloughing of the bladder wall, and is apt to assume the membranous form described below. The most common example of a septic cystitis is that which occurs as a complication of gonorrhoea.

Gout is commonly looked upon as a cause of cystitis, but the part played by it to the disease is little understood.

Lastly, acute cystitis may occur without any obvious cause. It is usually attributed to exposure to cold, but it is doubtful whether this is the sole cause of the inflammation, except perhaps in gouty subjects.

The **Symptoms** of acute cystitis consist not only in local pain and tenderness in the hypogastric and iliac regions, with tenderness on pressure in these situations, and a good deal of constitutional irritation; but in the existence of extreme irritability about the bladder. As soon as a few drops of urine collect, they excite so much irritation that they cannot be retained, and are expelled by a kind of spasmodic or convulsive effort, constituting *strangury*, often accompanied by a good deal of tenesmus and great suffering. The urine will be found to be high-coloured, mixed with more or less mucus or pus, and often tinged with blood. The constitutional disturbance varies greatly; in the more severe septic and infective forms there may be considerable elevation of temperature, sometimes with rigors.

Pathological Changes.—The mucous membrane is swollen and reddened, these changes being most marked on the summits of the rugae. The membrane is often covered with a layer of mucus, pus, and phosphates. In some forms of septic cystitis with foul urine the surface of the bladder is lined by a thick membranous layer of inflammatory exudation and altered epithelium. This condition, to which the name “membranous” or “diphtheritic” cystitis has been applied, is most commonly met with in females, and in rare instances the false membrane has been passed by the urethra, forming a complete cast of the bladder. As a very rare result of acute cystitis the mucous membrane may slough over considerable areas, and separate in the form of shreddy masses, exposing the muscular tissue.

The presence of micro-organisms in the bladder can almost always be demonstrated in cases of acute cystitis. In 8 cases of puerperal cystitis Bumm found a diplococcus, resembling, but not apparently identical with, the gonococcus. The ordinary micro-organisms of suppuration are sometimes met with, and in a considerable number of cases the bacterium coli commune has been demonstrated.

Termination.—An acute attack of cystitis usually terminates in the chronic form of the disease, and thus gradually undergoes resolution. Occasionally, however, it terminates fatally; and when this is the case, the urine becomes excessively foul, and death takes place from septicæmia, suppurating kidney, or more rarely from peritonitis. The temperature, which at first may have been elevated, gradually falls, the tongue becomes brown and dry, the pulse rapid and weak, and the patient sinks into a drowsy semi-comatose state before death.

Should sloughing of the mucous membrane occur, collections of pus may form in the substance of the wall of the bladder and not unfrequently the

peritoneum is implicated, and diffuse peritonitis set up. Occasionally perforation occurs, with infiltration of urine in the deep areolar tissue of the pelvis. Very commonly the mischief extends to the ureters and kidneys.

Treatment.—The first step in the treatment is, if possible, to render the urine less irritating by diluting it by the free administration of barley-water or mucilaginous drinks, and by giving liquor potassæ or bicarbonate of potassium in doses sufficient to neutralize it. The patient must be confined to bed, and hot fomentations or poultices applied over the lower part of the belly. Long-continued hot hip-baths usually give great relief. To these means may be added the administration of hyoscyamus in full doses and morphia suppositories. No specific medicines are of any use. No instruments should be used during acute cystitis if they can possibly be avoided; but should the urine become foul, an attempt may be made to wash out the bladder, as the mechanical irritation of the catheter is a lesser evil than an accumulation of putrid mucus and urine. If it be necessary to do this, great gentleness must be used, the quantity of fluid injected being limited to about an ounce. The diet must be carefully regulated; no salt or spiced food must be allowed. As a rule a pure milk diet will be found the best.

In some severe forms of membranous cystitis occurring in females it has been recommended to clear out the bladder through the dilated urethra and apply a strong solution of nitrate of silver.

CHRONIC CYSTITIS.—Chronic cystitis is by far the most common morbid condition of the bladder. It may follow acute inflammation, the intensity of the process gradually subsiding, or it may from the first be chronic. It is met with in all cases of stone in the bladder after the disease has existed for a certain time; in all old and tight strictures; and it is the inevitable consequence of the presence of decomposing urine in the cavity of the bladder. In some cases it is apparently of gouty origin; but perhaps the most persistent form is that which sometimes follows gonorrhœa, which may be acquired in youth, and lead to life-long misery.

Pathological Changes.—On examining the bladder of a patient who has suffered from chronic cystitis, the mucous membrane will usually be found to be of a dark grey or slate colour. As in most cases there has been some exacerbation of the condition immediately before death, dark red or purple patches are usually seen in various parts, especially on the summits of the rugæ. Dilated and tortuous veins commonly ramify on the surface, the blood in which is usually blackened by the contact of the decomposing urine after death. The mucous membrane is tougher and thicker than natural, and not uncommonly there is distinct thickening with induration of the submucous tissue. Ulceration of the mucous membrane is occasionally met with. The muscular coat of the bladder is seldom unaltered, as in the great majority of cases chronic cystitis is associated with conditions which interfere with free micturition. If the obstruction has been of such a kind that no amount of increased force could have emptied the bladder, as in many cases of enlarged prostate, the bladder is dilated, and its muscular coat may be thinned and atrophied with an excess of fibrous tissue between the muscle fibres. In cases of stricture of the urethra, and other obstructions which can be overcome by increased force, the bladder is usually contracted, and its muscular wall greatly hypertrophied and thickened. The hypertrophied fasciculi of muscular tissue form ridges beneath the mucous membrane, having irregular depressions

between them, so as to cause the interior of the bladder to resemble somewhat the inside of one of the cavities of the heart, with its projecting columns carneæ. The hypertrophy is usually dependent on the same cause that has given rise to the chronic inflammation, but in some cases cystitis alone may cause the hypertrophy. It would, then, seem to be due to the obstruction caused by the thick ropy mucus, which requires greater force for its expulsion than healthy urine, and it is consequently only an indirect effect of the inflammation. Sacculi are commonly found projecting at the posterior and lateral parts. These are of two kinds, both of which are formed by projections between the fasciculi of the wall of the bladder. In the first and less common kind, the muscular as well as the mucous coat is pushed outwards; in the second form, the mucous coat alone forms a kind of hernial protrusion (Fig. 900). In the sacculi thus formed accumulations of various kinds may take place: mucus, pus, phosphatic deposits, and even calcareous concretions, not unfrequently being met with. The urine, mixed with mucus and pus, retained in these pouches, readily undergoes decomposition, and the difficulty in cleaning such a sacculated bladder by injections is great. Sometimes ulceration of a sacculus takes place as a consequence of the irritation of the fetid accumulation, and perforation may occur, followed by peritonitis and death. Ulcerations of the mucous membrane and abscesses in the submucous tissue are occasionally met with in bladders which have suffered from chronic cystitis, but they are usually the result of the exacerbation that often sets in before death. The effect of chronic cystitis in causing disease of the kidney has already been described (p. 992).

Fig. 900. —Sacculus in the Wall of the Bladder

The **Symptoms** of chronic cystitis closely resemble those of the acute form, differing only in degree. The bladder is unable to bear more than a slight degree of distension without pain, consequently there is a frequent desire to pass water, and the urgency is such that the slightest delay gives rise to considerable suffering. This *pain before micturition* is always one of the most prominent symptoms. The fluid is generally ejected forcibly or even spasmodically, and in small quantities at a time. Its passage may be attended with some pain, but seldom enough to be termed strangury. If the cystitis is not complicated by stone there is distinct relief after micturition. The urine is turbid, and always contains an excess of mucus. In slight cases this is small in amount, but more commonly it becomes abundant and viscid, requiring some force and straining for its expulsion, forming the condition known as *Catarrh of the Bladder*. The urine then, unless special means are taken to prevent it, becomes ammoniacal and fetid, and is often mixed with much pus. The urine, on standing, separates into two parts, the upper being clear, but the lower consisting of a thick, viscid, slimy, or gummy mucus, often semi-opaque and purulent in appearance; it sticks tenaciously to the bottom of the vessel, and when poured out hangs from the edge in long stringy masses. It often contains triple phosphate crystals in large numbers. The alkaline condition of the urine in vesical catarrh is due to the formation of ammonium carbonate from decomposition of the urea. The cause of this change is a question of great importance, as the irritation of the ammoniacal urine in the bladder is one of the most important causes of the persistence of vesical

Catarrh. It is generally recognized that it takes place by a process of fermentation, but the exact nature of the ferment has been a matter of dispute. All urine undergoing ammoniacal fermentation is found to contain microscopic organisms, often of various kinds. The most constant is a small micrococcus, but with this, rod-shaped organisms showing active movements are almost invariably present. These organisms are very generally regarded as the actual ferment, and they are supposed to be carried into the bladder in most cases by instruments used in the treatment of the various conditions upon which the cystitis is dependent. The evidence in favour of this view cannot be fully discussed here, but it may be stated briefly that experiments by Lister and others have shown that healthy urine drawn from the bladder, with proper precautions against the admission of organisms from the air, into vessels which have previously been heated or exposed to the flame of a spirit lamp, shows no tendency to undergo spontaneous decomposition, and may be preserved for months in contact with filtered air without becoming ammoniacal. It is not uncommon, moreover, in practice, to meet with cases in which the patient has been unable to empty his bladder completely for many months in consequence of prostatic disease, and yet the urine has remained acid and free from decomposition throughout; at last a catheter is passed, and within three days the urine is decomposing and strongly ammoniacal. Cases are, however, not unfrequently met with in which the urine is foul, and yet no instrument has ever been passed. In these the explanation suggested is that the mucus secreted as the result of cystitis hangs in the urethra, which is not washed clean at every act of micturition, and constantly forms a channel of communication between the external air and the bladder by means of which decomposition may extend into the bladder. Urine which is mixed with a considerable proportion of alkaline mucus decomposes far more readily than the healthy secretion.

The constitutional symptoms of chronic cystitis are chiefly due to the disturbance at night and want of rest, unless the urine is allowed to become foul. If this happen, the ordinary symptoms of chronic septic poisoning usually manifest themselves—irregular febrile disturbance, loss of appetite, foul tongue, and progressive emaciation.

Chronic cystitis is not unfrequently fatal, death resulting in most cases from septicaemia, or from extension of decomposition to the urine in the ureters and pelves of the kidneys with suppurative nephritis. These conditions are accompanied by the symptoms already described. Occasionally, in old patients, the constant disturbance may cause death by exhaustion.

The **Treatment** of chronic cystitis must always have reference to its cause. If it be due to stone or stricture no permanent improvement can be obtained till these causes are removed, but before undertaking this, if the symptoms are verging on those of the acute form, hot hip-baths, fomentations, mucilaginous drinks, hyoscyamus with alkalies, and especially potash, will be found most useful. The bowels must be kept regular by enemata or castor oil. If there should be strangury, morphia or belladonna suppositories will give most relief. By these means the disease may be prevented from assuming the form of chronic vesical catarrh; but in order to ensure this it is most important that decomposition of the urine should be prevented, or if it have already commenced that it should be arrested. For the prevention of the decomposition all instruments should be washed in carbolic acid lotion (1 in 40) before being

used, and then greased with "Lund's oil," composed of absolute phenol, 1 part, castor oil, 4 parts, and olive oil, 15 parts; or with the following, which has the advantage of not crystallizing in winter: absolute phenol, 1 part; castor oil, 7 parts; and almond oil, 8 parts. The penis should also be washed with boric acid or carbolic acid lotion after micturition and covered with lint soaked in glycerine of carbolic acid or a piece of salicylic wool. If the urine has once become foul it becomes necessary to adopt local means to correct it. No good can be expected from medicines so long as the bladder is full of putrid mucus and urine. The bladder must therefore be washed out with some antiseptic solution, once, or, if necessary, twice daily. This is done as follows: a soft catheter is passed and the urine drawn off; about two ounces of fluid are then thrown in from an india-rubber bottle fitted with a brass nozzle and stop-cock. The fluid is then allowed to run out again, and this is repeated till that which comes back is quite clean. Nothing is gained by injecting larger quantities, which only cause needless pain and irritation. There is another method of washing out the bladder which will often be found useful. It consists in attaching an india-rubber tube, about three feet long, to the catheter. At the other end of the tube is a glass funnel. By raising the funnel about two feet above the patient's body and pouring the fluid into it, sufficient force will be obtained to fill the bladder. When sufficient fluid has entered, the funnel may be allowed to hang over the side of the bed over a vessel, when the fluid will be withdrawn from the bladder, the tube acting as a siphon. Amongst the most useful of all antiseptic injections is permanganate of potash; the solution may be injected repeatedly till it comes back purple. Its effect is, however, very temporary, and it is well after the bladder has been cleaned by Condry's fluid and water to throw in a small quantity of some more powerful antiseptic. Perhaps the best of these is quinine, in the strength of two to three grains to the ounce of water, with a minim of dilute sulphuric acid added for each grain; of this about one drachm may be left in after the catheter is withdrawn. Other antiseptics are also useful, as boric acid (a concentrated solution); perchloride of mercury (gr. $\frac{1}{8}$ to 3j.); a concentrated solution of thymol; dilute nitric acid (m. ij. to 3j.), &c. One of the most efficient of all antiseptics I have found to be iodoform, in the proportion of from two to four grains to the ounce of water, with a little mucilage to suspend it.

Various drugs may be administered internally with the object of arresting the decomposition of the urine. The best known of these is benzoic acid, which is discharged with the urine in the form of hippuric acid; it may be given in ten-grain doses three or four times a day, either in a pill or in a mixture containing mucilage to suspend it.

Betol, the salicylate of β naphthol ether, may be given in three to eight-grain doses in cachets or pills. Saccharin in one-grain doses has also been found useful, if the urine is foul. Salol is somewhat extensively used, although Mansel Sympton has pointed out that the drug is dangerous if there is advanced kidney disease; five grains may be given three times a day or oftener, either in pills or suspended with mucilage. Boric acid is sometimes useful; ten grains should be given three times a day.

When by these means the urine has been brought into a tolerably healthy condition, so far as putrefaction is concerned, there still may continue a considerable excess of mucus which renders it prone to decompose, and unless constant care is exercised the patient may speedily relapse. To check this

various astringent injections are sometimes of use, such as tannin (gr. j to 3j); acetate of lead (gr. $\frac{1}{4}$ to 3j); or nitrate of silver (gr. $\frac{1}{4}$ to 3j).

Simultaneously with antiseptic or astringent injections, medical treatment may also be carried out. The greatest benefit will be derived from stimulating and balsamic diuretics such as buchu, uva ursi, and triticum repens; but these remedies are useless, unless taken in quantities of a pint or a pint and a half in the day. The best of these is buchu. The infusion should be made freshly every day by putting half an ounce of the leaves in a tea-pot and pouring a pint of boiling water on them. It should be taken cold, and the whole pint consumed in the 24 hours. When the disease is very chronic no remedy appears to me to possess so much influence over the mere ropy mucoid discharge as the balsam of copaiba. Turpentine, cubebs, and tincture of the sesquichloride of iron, will be found useful. It is often difficult to say beforehand which diuretic will suit best, and I can lay down no precise rules to guide the practitioner in this respect. But they may often be tried or alternated with advantage. In many cases great relief is obtained from each new remedy, but it is not maintained.

The diet must be very carefully attended to; no hot or spiced food should be allowed, and little or no salt. Alcoholic stimulants are better entirely avoided, but should any be required weak gin, or Hollands and water, or whisky and water are the best. Coffee must be strictly forbidden, but weak tea may be taken. Much benefit may often be derived from a pure milk diet for some weeks if the patient can bear it; if it prove too rich the cream may be taken off. A course of one of the alkaline mineral waters may sometimes prove of service, especially in gouty subjects. The body must be warmly clothed and all exposure to cold avoided.

IRRITABILITY OF THE BLADDER.

Irritability of the Bladder is not a disease; it is merely a symptom. It is of very frequent occurrence and is met with at all ages, and arises from a great variety of causes. It consists in a frequent desire to pass water, not dependent on an increase in the quantity of the secretion. The desire is usually so urgent as to amount to actual pain, and in extreme cases it is impossible to delay the act by any voluntary effort. The urine is generally ejected forcibly, or even spasmodically, and in small quantities at a time. It may or may not be attended with strangury, according to the cause and the part affected. Strangury is most marked in those cases in which it is due to disease of the prostate or neck of the bladder. In some persons frequency of micturition may be merely a habit. It then occurs in the day only. If a patient is disturbed more than once at night to pass water true irritability exists.

The **Causes** of irritability of the bladder differ somewhat as the affection occurs in men, in women, or in children. In *men* they may be arranged under the following heads:—

1. *Morbid Conditions of the Urine.*—If this secretion be preternaturally acid and loaded with urates or uric acid, it is especially apt to occasion an irritation of the bladder, attended with pain and a frequent desire to micturate. Urine containing oxalates in large quantity is sometimes, though more rarely, a source of irritability of the bladder, which in these cases is perhaps increased by the morbidly sensitive state of the nervous system sometimes co-existing

with these conditions of the urine. Amorphous phosphates passed at the end of micturition may cause severe pain, with a constant desire to pass water, lasting for an hour or less. It ceases as soon as the "alkaline tide" in the urine has passed (p. 1029).

In *gout*, irritability of the bladder is not unfrequently met with. This may in some cases be owing to the acid character of the urine; in others, to gouty inflammation of the bladder or prostate.

2. *Renal disease*, more particularly the lodgment of a stone in the kidney, will often occasion sympathetic pains in the bladder, with much irritability of that organ, so as closely to simulate vesical disease, or even to lead to a suspicion of the existence of stone in the bladder. Tuberculous pyelitis will give rise to similar symptoms; in fact, in some cases the frequency of micturition may be greater than in almost any other affection of the urinary organs.

3. *Disease of the Bladder itself*, as a chronically inflamed state of its mucous membrane, will give rise to pain and irritation on the accumulation of a small quantity of urine, with a frequent desire for its expulsion. So, also, when the bladder is fasciculated, or sacculated, and more especially if there be a tumour in a state of ulceration, most severe and intractable irritability may be induced.

4. *A Stone in the Bladder* will always, by its mechanical action, by its weight and pressure, by rolling about when the body is in motion, irritate the interior of the organ; and, in fact, the "rational symptoms" of stone in the bladder are simply those of irritability of that organ.

5. *Inflammation, Ulceration, Abscess, Tubercle, or other Diseases of the Prostate*, and inflammation, gonorrhoeal or simple, and abscess or stricture of the deeper portions of the urethra, also not unfrequently occasion irritability of the bladder.

6. *Various Diseases in Neighbouring Organs* will occasion this condition. Amongst the most frequent are fissure and ulcer of the rectum and anus, piles, prolapsus recti, intestinal worms, gall-stones, and varicocele.

The **Diagnosis** of irritability of the bladder is made by the patient himself: but it is often a matter of no little difficulty to the Surgeon to ascertain the precise cause of that irritability. This can of course be done only by a careful exploration of the whole of the urinary organs, and often of the neighbouring parts; no mere inquiry into the nature of the symptoms can do more than establish the fact of the existence of "irritability of the bladder," and afford some evidence of a negative kind as to the absence of certain causes. Nothing short of a careful exploration of the urethra, prostate, and bladder, by means of the catheter, finger, and sound, and cystoscope, can enable the practitioner to state with absolute certainty on what the irritability depends. I have repeatedly seen cases of stone in the bladder, and of prostatic disease, vainly treated for months as cases of simple "irritability of the bladder;" the existence of the real cause of the symptoms having been overlooked altogether, until a proper examination of the urinary organs was instituted. So closely, in fact, do the symptoms of vesical irritation, arising from gout, or sympathetic with kidney disease, simulate those that are occasioned by stone in the bladder, that it is impossible for the most experienced medical practitioner to refer them with certainty to the right cause without exploring this cavity. I have known several patients who had been operated on for stone, and who, some years afterwards, suffered from gouty irritability of the bladder, imagine, but erroneously, that they were labouring under a

recurrence of the calculus, so closely do the two classes of symptoms coincide in character.

Cases, however, will be met with now and then, in which, in spite of the most careful examination and prolonged observation, no tangible cause will be found for the irritability of the bladder.

In the **Treatment** of irritability of the bladder it must be borne in mind that this condition is not a substantive disease, but an assemblage of symptoms resulting from the influence of a great number of very various causes, which must first be removed before the bladder can recover its normal sensibility and tone. When once the occasioning cause has been removed, whether that be a calculus, or gout, or prostatic disease, or a pile, such local vesical irritability as may remain may be removed by alkaline and mucilaginous drinks. Sedatives may be of use ; some in one case, others in another. Opium and belladonna, either by mouth or in suppository, are amongst the best. Hyoscyamus, or Indian hemp, suits some patients ; and chloral is one of the most generally useful remedies. The diet should be carefully regulated, and warm hip-baths used frequently. In cases in which no tangible cause can be found and removed, and which prove hopelessly intractable to every means of treatment, local and constitutional, nothing can be more miserable than the state of the unfortunate victim of an "irritable bladder." Under these circumstances, much relief may be given by temporary drainage of the bladder. This may conveniently be done in the following manner, as practised by Thompson : An ordinary curved median staff is first passed into the bladder, and the patient is tied up in the lithotomy position. The Surgeon then introduces his left forefinger into the rectum and feels for the apex of the prostate. He then takes a long narrow-bladed straight bistoury, and makes an incision about one inch and a quarter long in the middle line of the perinæum, terminating about three-quarters of an inch from the margin of the anus. The knife is then turned with its back to the rectum and entered near the lower end of the superficial incision. Guided by the finger in the rectum, the knife is then pushed steadily on till it enters the groove of the staff near the apex of the prostate. By drawing it forwards in the groove the membranous part of the urethra is opened. The knife may now be withdrawn, cutting slightly forwards in so doing, care being taken not to wound the bulb more than can possibly be avoided. Thompson then introduces a blunt gorget-like director with a beak to run in the groove. An ordinary long steel director, or a long probe, may be used instead if this instrument be not at hand. The staff being withdrawn, the finger is gently pushed along the director into the bladder. The operation is, in fact, nothing more than the ordinary median operation for lithotomy as performed by Allarton. By careful examination of the interior of the bladder with the finger, it may be possible to detect some cause for the symptoms, and to apply appropriate treatment. But even when no cause is detected many patients are greatly relieved or even cured by draining the bladder for a few days with a tube. In some cases of this nature an exploratory suprapubic cystotomy has been performed ; it is a more severe operation, but the opening is more conveniently placed for a thorough exploration of the bladder.

Irritability of the Bladder in Boys may, as in adults, arise from a variety of causes. Among the less common is stone, but this should always be excluded, first by careful sounding lest time be lost in useless treatment of

ATONY OF THE BLADDER.

By **Atony of the Bladder** is meant such a degree of weakness of this organ that its power of emptying itself is partially or wholly lost. It is in the great majority of cases a condition of old age, and is not to be confounded with paralysis of the bladder, such as occurs in cases of injury or disease of the spinal cord. In atony the nervous supply is unimpaired; it is the muscular tissue that is at fault. The muscular tissue of the bladder may be impaired from several causes. By far the most common is the chronic strain to which it is exposed in over-distension of the bladder from mechanical obstruction at its neck arising from enlargement of the prostate. In this condition, if the dilated bladder be examined microscopically, its walls will be found to contain a great excess of somewhat dense fibroid tissue, amongst which lie scattered patches of muscular tissue.

* In some rare cases atony of the bladder may result from a single prolonged voluntary or involuntary over-distension. The structural changes just described would then of course not be present.

Besides these, there is another variety of atony of the bladder commonly met with in early middle life, though it may occur at any age. In all the cases in which I have seen this form of atony it has been the consequence either of gonorrhoeal cystitis or of cystitis following lithotrity. It may lead to partial or complete retention. It is often, but not always, associated with vesical catarrh and fetid urine. This condition, when once it has become chronic, is, I believe, incurable. In it structural changes take place in the bladder consequent upon the extension of the chronic inflammatory process from the mucous membrane to the submucous tissue and muscular coat. Its walls become thickened, rugged, and pouched. The bladder is able neither to retain the normal amount of urine, nor completely to empty itself. The retained urine usually undergoes decomposition, and this condition is very apt to end in fatal disease of the kidneys.

Excluding all these conditions, there is yet another form of atony of the bladder which may be regarded as the most typical variety. It is essentially a condition of old age, and appears to be a senile degenerative change analogous to that of the heart and other organs so commonly met with at that time of life. Such a change occurring in a bladder occasions its distension from slight causes of obstruction which could readily be overcome by the healthy organ of a younger man. Thus, we not unfrequently see a dilated atonic bladder occurring as the result of stricture of the urethra in an old man, instead of the contracted hypertrophied organ commonly met with as the result of this disease. A strong bladder may overcome a moderate amount of obstruction to the escape of the urine; an atonic bladder utterly fails to do so. Thus, we see that a condition of atony of the bladder may occur in an otherwise healthy man from the obstruction of prostatic disease, while, on the other hand, a degree of obstruction that would be harmless to a healthy man may cause serious symptoms in one whose bladder is atonic to begin with. It is difficult to determine in most cases which is to be regarded as the primary condition.

The fact that atony of the bladder is rarely met with in women would suggest that in the great majority of cases mechanical obstruction from enlargement of the prostate is to be regarded as the primary factor in the production of the disease.

Symptoms.—When this condition comes on slowly as the result of advancing years, the patient usually finds that the urine escapes in a dribbling manner; that there is some difficulty, and at last an impossibility, in emptying the bladder completely; that there is not that forcible ejection of the last drops of urine that is characteristic of a healthy tone in the organ; at the same time, there is not unfrequently a tendency to the dribbling away of a few drops towards the end of micturition, and after its apparent cessation. The patient feels a desire to pass water more frequently than usual. He cannot retain his urine for more than an hour or two; he is often disturbed during the night, and if he does not at once obey the impulse, is apt to wet his clothes. This frequent desire to pass water is due to the bladder never emptying itself, a certain quantity—several ounces—of residual urine being left behind; by the addition of a small quantity the bladder becomes overloaded, and the desire to micturate is felt. Temporary relief is afforded, but as secretion continues the bladder soon fills up again, and so the process goes on. When complete retention occurs, the bladder slowly rises out of the pelvis into the hypogastric region, reaching even as high as the umbilicus. On examining the lower part of the abdomen, the organ will be felt hard, elastic, rounded, and pyriform in shape, projecting above the pubes, and feeling much like an enlarged uterus. In this situation, also, percussion will elicit a dull sound; on exploring the part through the rectum, the bladder will be found to project in this direction also; and on tapping with the fingers above the pubes, fluctuation may be felt through the wall of the gut.

The distension of the bladder is sometimes so very gradual and slow that the over-distended organ has been mistaken for an abdominal tumour. The urine dribbles away, and no pain and but little inconvenience is felt. Oedema of the legs may occur from pressure on the iliac veins.

Atony of the bladder is a sufficient cause for incomplete retention of urine. But it does not appear to be adequate to explain the complete retention with distension of the bladder that is commonly seen. For this to occur there must be some mechanical obstacle, however slight, to the outward flow of the urine—contraction of the neck, or an enlarged prostate. Could complete retention occur from a merely atonic bladder, we should meet with it as frequently in women as in men. It is the mechanical obstacle at the neck of the male bladder which intensifies the effects of its atony and leads to the complete stoppage.

After the bladder has once become distended, the retention may be complete, but it more commonly happens that a quantity of urine continues to dribble out of it; in fact, the amount that escapes in this manner may be very considerable, though the retention continue unrelieved. This *retention with dribbling* is a condition of great practical importance, as the continued escape of urine may lead the patient, and even the Surgeon, to overlook the true state of things; the more so, as in elderly people retention slowly induced often occasions but little inconvenience. I have drawn off nearly a gallon of urine from a patient in whom it had not been suspected that retention existed, in consequence of the continuance of this dribbling. In women

retention is not by any means so common as in men, but the bladder will sometimes attain an enormous size, rising as high as the umbilicus ; and such large bladders have been tapped under the supposition that the tumour was an ovarian cyst, or some similar growth. I once witnessed such a case in which the Surgeon, to his surprise, on tapping the tumour, drew off a quantity of clear and healthy urine, instead of ovarian fluid ; fortunately no bad effects followed. This retention with dribbling occurs in consequence of the bladder, as it rises out of the pelvis, elongating its neck ; and as the body becomes bent forward over the pubes a sharp curve or angle is formed at the junction of the neck and body of the viscus, through which a small stream of urine continues to dribble away, and escapes rather by its own gravity than by any expulsive effort on the part of the patient.

Diagnosis.—Retention from *Atony* can easily be distinguished from retention from *Obstruction*. In the former, on introducing the catheter when the patient is lying on his back, the instrument will not only readily enter, but the urine will simply flow out in a slow uniform stream, not being projected in a jet by the contraction of the walls of the organ, but rising and falling in obedience to the respiratory movements, or to the contractions of the abdominal muscles. In retention from obstruction, some difficulty will be experienced in passing the instrument at some one point, either in the urethra or at the prostate ; and when once it is introduced into the bladder, the urine will escape in a free and far projected stream. .

Results.—The habitual retention of a small quantity of urine in an atonic bladder which is incapable of discharging completely the whole of its contents occurs much more frequently than is suspected. The quantity thus retained will vary from an ounce to half a pint—the patient believing that he has emptied his bladder. The existence of this residual urine is readily determined by the introduction of a catheter after the patient thinks he has emptied his bladder. In consequence of the bladder never being completely emptied, there will be frequent, sudden, and almost irresistible calls to pass urine, so as to simulate irritability of the bladder. The retained urine becomes offensive, ammoniacal or fishy in odour, and mixed with mucus or muco-pus. The constituents of the urine become re-absorbed or are not excreted, derange the health, give rise to impaired nutrition, and, being eliminated by the skin, irritate it and occasion intractable forms of skin disease. I have seen chronic eczema of the most inveterate character produced in this way, and yield to treatment only on care being taken to keep the bladder clear and free from residual urine.

The effects of the presence of retained urine and of retention with dribbling are not identical. When retained urine is constantly present the general health suffers, the patient becoming slowly poisoned by the inability to get rid of an excretion. In retention with dribbling the danger is more immediate, and directly dependent on the liability to secondary disease of the bladder and kidneys. Subacute cystitis occurs as the result of the continued over-distension of the bladder. The symptoms are such as are described at p. 1003 as being indicative of urinary fever. The patient suffers from chills or slight rigors followed by depression and low spirits. Fever of a typhoid type comes on, with brown tongue, occasional retchings, mild delirium, and great prostration. This condition occurring in an aged man long suffering from atony of the bladder, with most probably an unsound state of the kidneys secondary to

chronic retention from atony of the organ or by extravasation of urine as in other forms of more acute

retention, except in the few cases that arise from inflammation. It is dependent upon senile changes in the bladder that may be relieved but cannot be cured. This state arises from the retained urine, even when it is complete. So long as this residual urine is present. Even when it accumulates so as to give rise to no symptom beyond frequency of micturition, however, the over-distension causes some irritation. The urine becomes cloudy from excess of mucus. Hematuria then frequently takes place, either from irritation of the urethra or after the passage of instrument. It must not be supposed that mere retention of urine in each act of micturition is sufficient in itself to cause irritation. It is more common than to find patients who have been catheterized for many months, and whose urine is yet perfectly normal. The statement sometimes made that death may follow till after an instrument has been passed, is not true. In the great majority of cases the urine becomes infected after surgical interference. When this takes place all the symptoms of acute cystitis supervene. Febrile disturbance, delirium, poisoning sets in, and death may follow. This is especially liable to happen when the kidneys are affected by chronic disease, as already pointed out (p. 994), is a common complication of the bladder.

The treatment in ordinary uncomplicated senile atony of the bladder is the removal of the patient from the residual urine, which he is no longer able to void. This can be done only by the use of the catheter, and the surgeon should teach the patient how to use this instrument so that at all times he may be the master of his own situation, and when necessary.

The period of "catheter life," as it has been appropriately termed, is an important period in a man's existence. For when the treatment has been begun, it can rarely be discontinued. It is often discontinued unnecessarily early. But it is of at least equal importance to avoid the opposite error of delaying its use too long, lest the urine should accumulate to such an extent as to become a source of injury to the patient, of injury to his general health, and of the development of cystitis and all its concomitant evils.

In cases of atony of the bladder for the removal of the urine, the simplest, and, if the kidneys be sound and the most reliable, is unattended with any danger. The safest catheter is the simple soft red rubber catheter will often pass with the least resistance. It is the best instrument to use. Metallic instruments, especially the long prostatic catheter, and should never be employed by the patient. The simple soft red rubber catheter, or the conical one with a flange, will be found most convenient if the rubber

instrument will not pass. This should be passed whilst the patient is standing up, with every possible care and gentleness. The instrument should be lubricated with an antiseptic oil. After and before use the instrument must be washed in cold carbolized water, so that all chance may be avoided of septic material being carried into the bladder, and thus leading to putrefaction of the urine. At first it may be quite sufficient if the residual urine is drawn off every third or second day. After a time this will be required once or twice daily. Until the patient becomes accustomed to the use of the catheter all unnecessary exertion, fatigue, and, above all, chills, should be most carefully avoided. When once the habit has been established, these precautions may be relaxed, *provided there is no evidence of renal disease*, and the urine continues clear and healthy.

The catheter must not be retained, lest it occasion subacute cystitis. If, as often happens in senile atony, the prostate is somewhat enlarged, care must be taken that the catheter really enters the bladder, and that the dilated prostatic urethra be not alone emptied. The weight of the residual urine causes the fundus of the bladder to pouch behind the prostate. This pouch must be thoroughly emptied by slowly withdrawing the catheter when the body of the bladder has been drained. Should subacute cystitis come on, with decomposition of urine, during the treatment, the bladder must be washed out after being emptied, with antiseptic lotions of the permanganate of potash, quinine, or iodoform.

When once a bladder has become atonic in advanced age, it never completely recovers its contractility, but the regular use of the catheter may do much to restore the normal contractility, in some degree at least. When once fairly established, "catheter life" may continue for many years without discomfort or appreciable danger. The general health must be attended to on ordinary principles; but no medicines are of any special service in these cases.

The treatment of that form of atony of the bladder, which arises in younger subjects, as the effect of gonorrhoeal cystitis or stone in the bladder, consists in the daily use of the catheter. *Nux vomica* may possibly be of use in some cases. Whenever the urine becomes turbid or offensive, antiseptic injections must be used. All this the patient may, in most cases, be readily taught to do for himself. When once he has acquired the art of auto-catheterism, he may pursue the ordinary business of life with comfort and without peril. But he must never relax his care of himself, lest subacute cystitis may come on, or phosphatic deposits form in the bladder.

INCONTINENCE OF URINE.

The term "incontinence of urine" is usually applied to all cases in which the urine is passed involuntarily. It occurs in three forms:—1. Passive incontinence, in which the urine dribbles away as fast as it is secreted, the bladder remaining empty. 2. Distension of the bladder with overflow. 3. Active incontinence, in which the bladder is emptied involuntarily at short intervals by its own contraction.

Passive Incontinence arises most commonly from paralysis of the neck of the bladder, from disease or injury of the spinal cord. It is occasionally met with in children from causes that are not clearly ascertained. Civiale states that it has been known to arise from impaction of a calculus in the

neck of the bladder in such a way as to prevent its closing, and yet to leave sufficient room for the urine to pass. Very rare cases have been recorded occurring in later life in which it was due to enlargement of the lateral lobes of the prostate, with a middle lobe situated between them in such a way as to keep them apart, and yet not to block the passage from the bladder. In tuberculous disease of the prostate, with extensive destruction of the gland, complete incontinence may occur. Passive incontinence is occasionally met with in women, as the result of dilatation of the urethra for the removal of stone.

2. **Distension of the Bladder with Overflow**, as it is termed by Thompson, may be due to atony of the bladder (p. 1121), or to enlargement of the middle lobe of the prostate. The effects of atony in causing overflow of urine have already been described; overflow from prostatic disease will be described subsequently. It is of the utmost importance that this condition should be distinguished from true incontinence.

3. **Active Incontinence** is met with most frequently in children, and is, as a rule, not constant, occurring only at night. It usually occurs in boys. It seems to arise in some cases from the patient losing command over the sphincter during sleep, as soon as a small quantity of urine has accumulated behind it. This troublesome condition may last to adult life, and is a source of great misery and discomfort. In children it is in many cases sympathetic, being dependent on the irritation of a tight foreskin, of worms in the rectum, or of a polypus. In other cases it may be merely a symptom of stone in the bladder. In strumous children, nocturnal incontinence may be produced by the irritation of urine containing uric acid crystals. All these conditions must be carefully sought for in every case, and removed if possible.

Treatment.—In true incontinence little can be done beyond providing the patient with a proper india-rubber urinal, which can be worn day and night. The treatment of overflow consists solely in the periodical use of the catheter (p. 1124). In nocturnal incontinence of children, if it be not connected with some evident source of local irritation, which should then be removed, the administration of tonics will be found useful—either quinine or the tincture of perchloride of iron, alone or conjoined with tincture of cantharides. If there be irritation of the mucous membrane of the bladder, the administration of alkalies, in conjunction with a tonic, as the potassio-tartrate of iron, or a little copaiba mixed with honey, will be found very serviceable. The last meal should not be immediately before bed-time, and the amount of fluid taken should be restricted. Cold sponging, light clothing at night, and means calculated to break the habit, such as waking the child at the time at which it generally occurs, changing his position in bed, &c., should not be omitted. Of all remedies for incontinence of urine in children, belladonna is the most successful. Ringer advises it to be given in full doses—from 10 to 20 minims of the tincture three times a day. Sometimes better results are obtained with atropine, which should be given at night in a dose gradually increased from each to as much as $\frac{1}{10}$ th of a grain. In obstinate cases the passage of a sound may be useful.

Hysterical Retention and Incontinence of Urine not unfrequently occur in nervous girls, and require to be treated by anti-hysterical remedies, amongst which preparations of perchloride of iron, either alone or with quinine, will be found most useful. Cold douches are also of great service.

In cases of hysterical retention, the use of the catheter should, if possible, be avoided, as the patients are apt to get into the habit of having it introduced, and will, with that morbid propensity that characterizes hysteria, continue for a length of time to require its introduction. If left to themselves, though the bladder may become much distended, it will not burst, but will probably empty itself without further trouble, particularly if the patient be put into a bath and well douched over the hips and loins with cold water. In some cases, these morbid conditions in women appear to be connected with some local irritation about the urethra or uterus; and then proper treatment must be directed to these organs before the disease can be removed.

Painful Conditions of the Bladder.—The bladder may be the seat of severe pain, either continuous or remittent, without any disease being discoverable in it; the pain being either a kind of neuralgic condition, especially occurring in hysterical or hypochondriacal patients; or else being sympathetic with, and dependent on, disease at a distance, as in the kidneys, uterus, rectum, &c. At the same time it must be borne in mind that the secretion of acid or irritating urine will, in some individuals, be a source of much constant suffering; and that any disease seated about, or coming into contact with, the neck of the bladder, as tumour, stone, &c., is especially apt to give rise to severe suffering, and will, in many cases, be accompanied by frequent desire to micturate, with much spasm about the part.

TUBERCLE OF THE BLADDER.

Tuberculous Disease of the bladder appears to be rarely primary. It is usually an extension from similar disease of the kidney and ureter, or of the prostate, and is not uncommonly met with as part of a general tuberculous affection of the genito-urinary tract. Even in cases in which all the symptoms during life are referable to the bladder, *post-mortem* examination will usually reveal the existence of tuberculous deposits elsewhere, especially in the prostate. The disease shows a special tendency to affect the parts about the trigone. It is rarely that the disease is seen in its earliest stages, when small granulations are present in the mucous membrane. Ulceration soon occurs, and in addition the signs of chronic cystitis become more or less marked. The ulcers are usually small and rounded or oval; the edges are slightly raised, and the surface is yellow and granular. Occasionally a single ulcer of considerable size is met with. The ulceration is usually superficial, and perforation of the bladder is rare. In the advanced stages of the disease the ulceration often extends to the neck of the bladder and the prostatic portion of the urethra.

Symptoms.—Tuberculous disease of the bladder has been met with at all ages, but it is most common in young adult males. The onset is often extremely insidious, and the only symptom in the early stages may be increased frequency of micturition. This may be so marked that care must be taken not to mistake it for incontinence, especially when the disease occurs in children.

Hæmaturia is frequently an early symptom, and thus at this stage the disease may possibly be confounded with stone or tumour of the bladder. Tuffier, writing in the "*Traité de Chirurgie*" of Duplay and Reclus, points out that the hæmorrhage may be distinguished from that due to stone by its

painlessness and the absence of any relation to rest and movement ; whilst from the hæmaturia due to a tumour it differs in its small amount and the period of increased frequency of micturition which usually precedes its first occurrence. In the later stages, when ulceration has occurred, the symptoms are those of chronic cystitis. The act of micturition is frequent and the pain severe. The urine contains pus, often in considerable quantity. At this stage the symptoms may closely resemble those of stone, and often the diagnosis is based chiefly upon the coexistence of tuberculous disease elsewhere, more especially in the kidneys, prostate and testes. The bacillus tuberculosis can occasionally be demonstrated in the pus in the urine. Cystoscopic examination may be useful as a means of diagnosis (p. 1110). The gravity of the case and the intensity of the patient's sufferings are much increased if the tuberculous affection become complicated with septic cystitis.

The prognosis is necessarily grave, especially if the affection of the bladder forms only part of a genito-urinary tuberculosis. In some cases, however, the course of the disease is very slow, and cure may undoubtedly occur as the result of local and constitutional treatment.

Treatment.—When the existence of early tuberculous disease of the bladder is suspected the general treatment should be carried out on the lines indicated in Vol. I., p. 1099. Guyon recommends, even in the early stages before symptoms of ulceration are present, instillations of perchloride of mercury. The solutions employed vary in strength from 1 in 200 to 1 in 1,000, and the amount injected from 10 to 40 drops. The bladder is emptied with a catheter and the injection made with a small syringe ; it may be repeated every few days.

In the later stages of the disease much may be done to relieve the pain and irritation by washing out the bladder ; and by the use of iodoform considerable improvement may sometimes be produced. Boric acid lotion will be found one of the most useful injections, and iodoform can best be introduced in the form of an emulsion. Berkeley Hill advised the following :—Iodoform 2 parts, mucilage 4 parts, glycerine 2 parts, water 20 parts ; two drachms to be injected once or twice a day. If the passage of the catheter and the washing out of the bladder cause much pain, a drachm of 5 per cent. solution of cocaine may be first injected. Cystotomy may be required in cases in which the simpler methods of treatment have failed, and in which the pain and irritability of the bladder are seriously affecting the patient's health. Not only does the drainage relieve the patient's symptoms, but by putting the bladder at rest the operation favours the healing of the ulcers, and also enables the Surgeon to treat the diseased surface directly. Median cystotomy is the simplest method, and this is probably the best treatment when the operation is undertaken merely as a palliative in advanced cases. In favourable cases, however, suprapubic cystotomy should be preferred, as it allows a more thorough examination ; and, if necessary, the ulcerated surface can be scraped and treated with iodoform. In a few cases this has been done with considerable success. In the female, direct treatment of the ulcers can be carried out after simple dilatation of the urethra, or by the use of Kelly's cystoscope.

SACculi OF THE BLADDER.

Sacculi have already been mentioned at pp. 992, 1041, and 1114, as arising in connexion with over-distension of the bladder or obstruction to the escape of urine from it. These are of small size, not usually exceeding a pigeon's egg. They arise, as already described, in the bladders of elderly men who have suffered from severe mechanical obstacle to the passage of the urine, in the shape of stricture or enlarged prostate; they are associated with a generally thickened fasciculated state of the organ, and appear to be the result of pressure on the contained urine during efforts at expulsion, causing extrusion of the mucous and serous coats, and perhaps of the thinned muscular coat at some points of least resistance.

Sacs connected with the bladder are, however, occasionally met with, the origin of which can hardly be explained in this way. These may be single or multiple, and may attain an enormous size. The largest I have seen occurred in a man 35 years of age, otherwise perfectly healthy. There was a tense elastic tumour, smooth and rounded, occupying the whole abdomen and extending into the pelvis, so as to be felt through the rectum. Had it occurred in a woman, the disease would probably have been pronounced to be ovarian. The tumour had existed for six months, had gradually increased, but occasioned no uneasiness except by its pressure-effects. There had been no difficulty in passing urine or in defæcation. The tumour was aspirated at its most prominent part, and seven pints of clear urine were drawn off. The patient suddenly became faint, and died of syncope. On examination after death, two enormous sacs were found connected with the bladder, one on each side, by a rounded opening that would admit the little finger. These orifices were equidistant from the mesial line, and about an inch and a half above each ureter. The sacs were thin-walled, composed chiefly of mucous membrane and peritoneum, possibly having scattered muscular fibres in their composition; both were emptied through the bladder by the one puncture. The ureter on each side was adherent to the wall of the sacculus and considerably pressed upon, and as the result of this the pelves of the kidneys were dilated; the pyramidal portion of the kidney was absorbed and the cortex greatly thickened and indurated by chronic interstitial inflammation. The bladder was greatly dilated and hypertrophied, its mucous membrane was opaque and white, and showed no signs of old or recent cystitis. The prostate and urethra were healthy, and no source of mechanical obstruction was detected. The cause of the condition is extremely obscure. There is a similar specimen, but somewhat less marked, in the museum of University College; the sacculus springs from the same spot, which indeed, from comparison with other specimens, seems to be the common point of origin of all sacculi of the bladder which reach any considerable size.

TUMOURS OF THE BLADDER.

SIMPLE TUMOURS.—The most common simple growth is the **Villous Tumour** or **Papilloma**. It consists of delicate branched processes, which, when the growth is immersed in water, float out, so that it somewhat resembles a sea anemone. These may spring from a narrow base forming a peduncu-

some other supposed cause. A long foreskin, especially with accumulation of smegma beneath it, or a phimosis, may give rise to considerable frequency of micturition and pain in a young boy. If neither stone nor phimosis be present the urine should be examined, and possibly a deposit of uric acid may be found, which is not uncommon in young children who are overfed or exposed to an impure atmosphere in a crowded city. If much mucus be present, or even pus, it may be due to chronic cystitis. This affection appears to be analogous to the strumous inflammations of the mucous membranes of the eyes, nose, and throat, that commonly occur in scrofulous children. In this condition the child passes water with great frequency and with much pain; the urine is offensive, and usually phosphatic; much uneasiness is complained of about the groins and along the penis; in fact, many of the ordinary symptoms of stone are present. On sounding the bladder, it will be found roughened, fasciculated, and often containing sabulous matters mixed with mucus. Occasionally, though rarely, tuberculous disease of the urinary tract is met with in children. It presents the same appearances as in the adult. Irritable bladder in children is very frequently due to thread-worms in the rectum, which should always be sought for in all doubtful cases. More rarely it may arise from the presence of a rectal polypus.

The **Treatment** consists in removal of the cause when this is possible. In the strumous affection of the mucous membrane, if the urine be foul, the bladder must if possible be cleaned out as in the adult, should the child be old enough for this to be done. The bladder may also be washed out from time to time with a weak solution of nitrate of silver. Beyond this the treatment consists in attention to the general improvement of the health, in the removal of intestinal irritation, in the regulation of the digestive functions, and in the administration of copaiba in small doses, either alone or conjoined with a few minims of liquor potassæ.

Irritability of the Bladder in Women often simulates stone so closely, that it is only after very careful sounding that the Surgeon is satisfied that no calculus exists. This condition may arise from a variety of causes, similar to those described at p. 1117, as occasioning irritability of the male bladder. There are some conditions, however, in which it occurs, that are peculiar to women: 1. It may be a truly neurotic or hysterical affection. 2. It is most commonly the result of enlargement of the body of the uterus from whatever cause, and is thus very frequent in early pregnancy. 3. Inflammatory affections in the pelvis, such as pelvic peritonitis, frequently occasion painful and frequent micturition. 4. It is often sympathetic; being connected with some local disease of the genito-urinary organs, such as a vascular caruncle of the urethra, which will require to be cured before the bladder can be brought into a healthy state. 5. Tumours of various kinds occupying the cavity of the pelvis may occasion irritability of the bladder by the traction exerted upon it. 6. Prolapse of the anterior wall of the vagina, drawing down the corresponding portion of the bladder, may occasion the condition, especially if the vesical pouch contains stagnant phosphatic urine. It may be relieved by the use of a pessary, or by a plastic operation. 7. In strumous girls it may be due to a congested and irritated state of the vesical mucous membrane, similar to that which is met with in boys (see above). It is commonly associated with a muco-purulent discharge from the vagina. In cases such as these, the patient requires to be put upon a general tonic treatment, and the bladder should be

mopped out with a very strong solution of the nitrate of silver. This is best done by dilating the urethra, passing a silver tube into the bladder, and then through it a small sponge-probang charged with the solution.

ATONY OF THE BLADDER.

By **Atony of the Bladder** is meant such a degree of weakness of this organ that its power of emptying itself is partially or wholly lost. It is in the great majority of cases a condition of old age, and is not to be confounded with paralysis of the bladder, such as occurs in cases of injury or disease of the spinal cord. In atony the nervous supply is unimpaired; it is the muscular tissue that is at fault. The muscular tissue of the bladder may be impaired from several causes. By far the most common is the chronic strain to which it is exposed in over-distension of the bladder from mechanical obstruction at its neck arising from enlargement of the prostate. In this condition, if the dilated bladder be examined microscopically, its walls will be found to contain a great excess of somewhat dense fibroid tissue, amongst which lie scattered patches of muscular tissue.

• In some rare cases atony of the bladder may result from a single prolonged voluntary or involuntary over-distension. The structural changes just described would then of course not be present.

Besides these, there is another variety of atony of the bladder commonly met with in early middle life, though it may occur at any age. In all the cases in which I have seen this form of atony it has been the consequence either of gonorrhœal cystitis or of cystitis following lithotrity. It may lead to partial or complete retention. It is often, but not always, associated with vesical catarrh and fetid urine. This condition, when once it has become chronic, is, I believe, incurable. In it structural changes take place in the bladder consequent upon the extension of the chronic inflammatory process from the mucous membrane to the submucous tissue and muscular coat. Its walls become thickened, rugged, and pouched. The bladder is able neither to retain the normal amount of urine, nor completely to empty itself. The retained urine usually undergoes decomposition, and this condition is very apt to end in fatal disease of the kidneys.

Excluding all these conditions, there is yet another form of atony of the bladder which may be regarded as the most typical variety. It is essentially a condition of old age, and appears to be a senile degenerative change analogous to that of the heart and other organs so commonly met with at that time of life. Such a change occurring in a bladder occasions its distension from slight causes of obstruction which could readily be overcome by the healthy organ of a younger man. Thus, we not unfrequently see a dilated atonic bladder occurring as the result of stricture of the urethra in an old man, instead of the contracted hypertrophied organ commonly met with as the result of this disease. A strong bladder may overcome a moderate amount of obstruction to the escape of the urine; an atonic bladder utterly fails to do so. Thus, we see that a condition of atony of the bladder may occur in an otherwise healthy man from the obstruction of prostatic disease, while, on the other hand, a degree of obstruction that would be harmless to a healthy man may cause serious symptoms in one whose bladder is atonic to begin with. It is difficult to determine in most cases which is to be regarded as the primary condition.

The fact that atony of the bladder is rarely met with in women would suggest that in the great majority of cases mechanical obstruction from enlargement of the prostate is to be regarded as the primary factor in the production of the disease.

Symptoms.—When this condition comes on slowly as the result of advancing years, the patient usually finds that the urine escapes in a dribbling manner ; that there is some difficulty, and at last an impossibility, in emptying the bladder completely ; that there is not that forcible ejection of the last drops of urine that is characteristic of a healthy tone in the organ ; at the same time, there is not unfrequently a tendency to the dribbling away of a few drops towards the end of micturition, and after its apparent cessation. The patient feels a desire to pass water more frequently than usual. He cannot retain his urine for more than an hour or two ; he is often disturbed during the night, and if he does not at once obey the impulse, is apt to wet his clothes. This frequent desire to pass water is due to the bladder never emptying itself, a certain quantity—several ounces—of residual urine being left behind ; by the addition of a small quantity the bladder becomes overloaded, and the desire to micturate is felt. Temporary relief is afforded, but as secretion continues the bladder soon fills up again, and so the process goes on. When complete retention occurs, the bladder slowly rises out of the pelvis into the hypogastric region, reaching even as high as the umbilicus. On examining the lower part of the abdomen, the organ will be felt hard, elastic, rounded, and pyriform in shape, projecting above the pubes, and feeling much like an enlarged uterus. In this situation, also, percussion will elicit a dull sound ; on exploring the part through the rectum, the bladder will be found to project in this direction also ; and on tapping with the fingers above the pubes, fluctuation may be felt through the wall of the gut.

The distension of the bladder is sometimes so very gradual and slow that the over-distended organ has been mistaken for an abdominal tumour. The urine dribbles away, and no pain and but little inconvenience is felt. *Cedema* of the legs may occur from pressure on the iliac veins.

Atony of the bladder is a sufficient cause for incomplete retention of urine. But it does not appear to be adequate to explain the complete retention with distension of the bladder that is commonly seen. For this to occur there must be some mechanical obstacle, however slight, to the outward flow of the urine—contraction of the neck, or an enlarged prostate. Could complete retention occur from a merely atonic bladder, we should meet with it as frequently in women as in men. It is the mechanical obstacle at the neck of the male bladder which intensifies the effects of its atony and leads to the complete stoppage.

After the bladder has once become distended, the retention may be complete, but it more commonly happens that a quantity of urine continues to dribble out of it ; in fact, the amount that escapes in this manner may be very considerable, though the retention continue unrelieved. This *retention with dribbling* is a condition of great practical importance, as the continued escape of urine may lead the patient, and even the Surgeon, to overlook the true state of things ; the more so, as in elderly people retention slowly induced often occasions but little inconvenience. I have drawn off nearly a gallon of urine from a patient in whom it had not been suspected that retention existed, in consequence of the continuance of this dribbling. In women

retention is not by any means so common as in men, but the bladder will sometimes attain an enormous size, rising as high as the umbilicus ; and such large bladders have been tapped under the supposition that the tumour was an ovarian cyst, or some similar growth. I once witnessed such a case in which the Surgeon, to his surprise, on tapping the tumour, drew off a quantity of clear and healthy urine, instead of ovarian fluid ; fortunately no bad effects followed. This retention with dribbling occurs in consequence of the bladder, as it rises out of the pelvis, elongating its neck ; and as the body becomes bent forward over the pubes a sharp curve or angle is formed at the junction of the neck and body of the viscus, through which a small stream of urine continues to dribble away, and escapes rather by its own gravity than by any expulsive effort on the part of the patient.

Diagnosis.—Retention from *Atony* can easily be distinguished from retention from *Obstruction*. In the former, on introducing the catheter when the patient is lying on his back, the instrument will not only readily enter, but the urine will simply flow out in a slow uniform stream, not being projected in a jet by the contraction of the walls of the organ, but rising and falling in obedience to the respiratory movements, or to the contractions of the abdominal muscles. In retention from obstruction, some difficulty will be experienced in passing the instrument at some one point, either in the urethra or at the prostate ; and when once it is introduced into the bladder, the urine will escape in a free and far projected stream.

Results.—The habitual retention of a small quantity of urine in an atonic bladder which is incapable of discharging completely the whole of its contents occurs much more frequently than is suspected. The quantity thus retained will vary from an ounce to half a pint—the patient believing that he has emptied his bladder. The existence of this residual urine is readily determined by the introduction of a catheter after the patient thinks he has emptied his bladder. In consequence of the bladder never being completely emptied, there will be frequent, sudden, and almost irresistible calls to pass urine, so as to simulate irritability of the bladder. The retained urine becomes offensive, ammoniacal or fishy in odour, and mixed with mucus or muco-pus. The constituents of the urine become re-absorbed or are not excreted, derange the health, give rise to impaired nutrition, and, being eliminated by the skin, irritate it and occasion intractable forms of skin disease. I have seen chronic eczema of the most inveterate character produced in this way, and yield to treatment only on care being taken to keep the bladder clear and free from residual urine.

The effects of the presence of retained urine and of retention with dribbling are not identical. When retained urine is constantly present the general health suffers, the patient becoming slowly poisoned by the inability to get rid of an excretion. In retention with dribbling the danger is more immediate, and directly dependent on the liability to secondary disease of the bladder and kidneys. Subacute cystitis occurs as the result of the continued over-distension of the bladder. The symptoms are such as are described at p. 1003 as being indicative of urinary fever. The patient suffers from chills or slight rigors followed by depression and low spirits. Fever of a typhoid type comes on, with brown tongue, occasional retchings, mild delirium, and great prostration. This condition occurring in an aged man long suffering from atony of the bladder, with most probably an unsound state of the kidneys secondary to

this, is commonly fatal. It is thus that chronic retention from atony of the bladder destroys life, not by ulceration of the organ or by extravasation of urine, which does not occur in these cases as in other forms of more acute retention.

Treatment.—Atony of the bladder, except in the few cases that arise from a single over-distension, is incurable. It is dependent upon senile changes in the viscus of an organic character that may be relieved but cannot be remedied. The great danger in this state arises from the retained urine, even though retention be by no means complete. So long as this residual urine is in small quantity no harm results. Even when it accumulates so as to amount to several ounces, it may give rise to no symptom beyond frequency of micturition. Sooner or later, however, the over-distension causes some irritation of the bladder, and the urine becomes cloudy from excess of mucus. Decomposition of the retained urine then frequently takes place, either from extension of decomposition up the urethra or after the passage of instruments, as already described. It must not be supposed that mere retention of a small quantity of urine after each act of micturition is sufficient in itself to cause decomposition. Nothing is more common than to find patients who have not emptied their bladders for many months, and whose urine is yet perfectly normal in every respect. The statement sometimes made that decomposition never takes place till after an instrument has been passed, is, however, not accurate, although in the great majority of cases the urine becomes ammoniacal only after surgical interference. When this takes place all the symptoms of chronic or subacute cystitis supervene. Febrile disturbance of the type of chronic septic poisoning sets in, and death may follow. This is more especially likely to happen when the kidneys are affected by chronic interstitial nephritis, which, as already pointed out (p. 994), is a common result of prolonged over-distension of the bladder.

The primary object of all treatment in ordinary uncomplicated senile atony of the bladder is to free the patient from the residual urine, which he is no longer able to expel. This can be done only by the use of the catheter, and it is the duty of the Surgeon to teach the patient how to use this instrument for himself, so that at all times he may be the master of his own situation, and relieve himself when necessary.

The commencement of "catheter life," as it has been appropriately termed by Sir Andrew Clark, is an important period in a man's existence. For when once the use of the instrument has been begun, it can rarely be discontinued. Hence it is well not to begin it unnecessarily early. But it is of at least equal importance not to fall into the opposite error of delaying its use too long, lest the residual urine be allowed to accumulate to such an extent as to become a source of discomfort to the patient, of injury to his general health, and of danger by inducing septic cystitis and all its concomitant evils.

The use of the catheter in cases of atony of the bladder for the removal of residual urine is very simple, and, if the kidneys be sound and the most ordinary precautions taken, is unattended with any danger. The safest catheter to use is a soft one. The simple soft red rubber catheter will often pass with ease, and is then by far the best instrument to use. Metallic instruments need not be used by the Surgeon, and should never be employed by the patient himself. The ordinary elbowed prostatic catheter, or the conical one with a bulbous end of medium size, will be found most convenient if the rubber

instrument will not pass. This should be passed whilst the patient is standing up, with every possible care and gentleness. The instrument should be lubricated with an antiseptic oil. After and before use the instrument must be washed in cold carbolized water, so that all chance may be avoided of septic material being carried into the bladder, and thus leading to putrefaction of the urine. At first it may be quite sufficient if the residual urine is drawn off every third or second day. After a time this will be required once or twice daily. Until the patient becomes accustomed to the use of the catheter all unnecessary exertion, fatigue, and, above all, chills, should be most carefully avoided. When once the habit has been established, these precautions may be relaxed, *provided there is no evidence of renal disease*, and the urine continues clear and healthy.

The catheter must not be retained, lest it occasion subacute cystitis. If, as often happens in senile atony, the prostate is somewhat enlarged, care must be taken that the catheter really enters the bladder, and that the dilated prostatic urethra be not alone emptied. The weight of the residual urine causes the fundus of the bladder to pouch behind the prostate. This pouch must be thoroughly emptied by slowly withdrawing the catheter when the body of the bladder has been drained. Should subacute cystitis come on, with decomposition of urine, during the treatment, the bladder must be washed out after being emptied, with antiseptic lotions of the permanganate of potash, quinine, or iodoform.

When once a bladder has become atonic in advanced age, it never completely recovers its contractility, but the regular use of the catheter may do much to restore the normal contractility, in some degree at least. When once fairly established, "catheter life" may continue for many years without discomfort or appreciable danger. The general health must be attended to on ordinary principles; but no medicines are of any special service in these cases.

The treatment of that form of atony of the bladder, which arises in younger subjects, as the effect of gonorrhoeal cystitis or stone in the bladder, consists in the daily use of the catheter. Nux vomica may possibly be of use in some cases. Whenever the urine becomes turbid or offensive, antiseptic injections must be used. All this the patient may, in most cases, be readily taught to do for himself. When once he has acquired the art of auto-catheterism, he may pursue the ordinary business of life with comfort and without peril. But he must never relax his care of himself, lest subacute cystitis may come on, or phosphatic deposits form in the bladder.

INCONTINENCE OF URINE.

The term "incontinence of urine" is usually applied to all cases in which the urine is passed involuntarily. It occurs in three forms:—1. Passive incontinence, in which the urine dribbles away as fast as it is secreted, the bladder remaining empty. 2. Distension of the bladder with overflow. 3. Active incontinence, in which the bladder is emptied involuntarily at short intervals by its own contraction.

Passive Incontinence arises most commonly from paralysis of the neck of the bladder, from disease or injury of the spinal cord. It is occasionally met with in children from causes that are not clearly ascertained. Civiale states that it has been known to arise from impaction of a calculus in the

this, is commonly fatal. It is thus that chronic retention from a bladder destroys life, not by ulceration of the organ or by extrusion of urine, which does not occur in these cases as in other forms of retention.

Treatment.—Atony of the bladder, except in the few cases of a single over-distension, is incurable. It is dependent upon some of the viscera of an organic character that may be relieved or remedied. The great danger in this state arises from the retention, though retention be by no means complete. So long as this is in small quantity no harm results. Even when it accumulates to several ounces, it may give rise to no symptom but of micturition. Sooner or later, however, the over-distension of the bladder, and the urine becomes cloudy from decomposition of the retained urine then frequently takes extension of decomposition up the urethra or after the urethra, as already described. It must not be supposed that a small quantity of urine after each act of micturition is a cause of decomposition. Nothing is more common than to have not emptied their bladders for many months, and yet perfectly normal in every respect. The statement that decomposition never takes place till after an instrument is, however, not accurate, although in the great majority of cases it comes ammoniacal only after surgical interference. When the symptoms of chronic or subacute cystitis supervene of the type of chronic septic poisoning sets in, and death is more especially likely to happen when the kidneys are affected by interstitial nephritis, which, as already pointed out, is the result of prolonged over-distension of the bladder.

The primary object of all treatment in ordinary cases of atony of the bladder is to free the patient from the residual urine, which is no longer able to expel. This can be done only by the use of the catheter. It is the duty of the Surgeon to teach the patient how to use it for himself, so that at all times he may be able to relieve himself when necessary.

The commencement of "catheter life," as it has been called by Sir Andrew Clark, is an important period in a patient's life. Once the use of the instrument has been begun, it is of great importance not to begin it unnecessarily early. Hence it is well not to begin it unnecessarily early. The importance is not to fall into the opposite error of allowing the residual urine to be allowed to accumulate to such an extent as to become a source of discomfort to the patient, of injury to the bladder, and of danger by inducing septic cystitis and all its consequences.

The use of the catheter in cases of atony of the bladder is very simple, and, if the ordinary precautions taken, is unattended with any special danger. To use is a soft one. The simple soft red rubber catheter is, and is then by far the best instrument for the purpose. It need not be used by the Surgeon, and should not be used by himself. The ordinary elbowed prostatic catheter with a bulbous end of medium size, will be found

painlessness and the absence of any relation to rest and movement ; whilst from the hæmaturia due to a tumour it differs in its small amount and the period of increased frequency of micturition which usually precedes its first occurrence. In the later stages, when ulceration has occurred, the symptoms are those of chronic cystitis. The act of micturition is frequent and the pain severe. The urine contains pus, often in considerable quantity. At this stage the symptoms may closely resemble those of stone, and often the diagnosis is based chiefly upon the coexistence of tuberculous disease elsewhere, more especially in the kidneys, prostate and testes. The bacillus tuberculosis can occasionally be demonstrated in the pus in the urine. Cystoscopic examination may be useful as a means of diagnosis (p. 1110). The gravity of the case and the intensity of the patient's sufferings are much increased if the tuberculous affection become complicated with septic cystitis.

The prognosis is necessarily grave, especially if the affection of the bladder forms only part of a genito-urinary tuberculosis. In some cases, however, the course of the disease is very slow, and cure may undoubtedly occur as the result of local and constitutional treatment.

Treatment.—When the existence of early tuberculous disease of the bladder is suspected the general treatment should be carried out on the lines indicated in Vol. I., p. 1099. Guyon recommends, even in the early stages before symptoms of ulceration are present, instillations of perchloride of mercury. The solutions employed vary in strength from 1 in 200 to 1 in 1,000, and the amount injected from 10 to 40 drops. The bladder is emptied with a catheter and the injection made with a small syringe ; it may be repeated every few days.

In the later stages of the disease much may be done to relieve the pain and irritation by washing out the bladder ; and by the use of iodoform considerable improvement may sometimes be produced. Boric acid lotion will be found one of the most useful injections, and iodoform can best be introduced in the form of an emulsion. Berkeley Hill advised the following :—Iodoform 2 parts, mucilage 4 parts, glycerine 2 parts, water 20 parts ; two drachms to be injected once or twice a day. If the passage of the catheter and the washing out of the bladder cause much pain, a drachm of 5 per cent. solution of cocaine may be first injected. Cystotomy may be required in cases in which the simpler methods of treatment have failed, and in which the pain and irritability of the bladder are seriously affecting the patient's health. Not only does the drainage relieve the patient's symptoms, but by putting the bladder at rest the operation favours the healing of the ulcers, and also enables the Surgeon to treat the diseased surface directly. Median cystotomy is the simplest method, and this is probably the best treatment when the operation is undertaken merely as a palliative in advanced cases. In favourable cases, however, suprapubic cystotomy should be preferred, as it allows a more thorough examination ; and, if necessary, the ulcerated surface can be scraped and treated with iodoform. In a few cases this has been done with considerable success. In the female, direct treatment of the ulcers can be carried out after simple dilatation of the urethra, or by the use of Kelly's cystoscope.

SACCU LI OF THE BLADDER.

Sacculi have already been mentioned at pp. 992, 1041, and 1114, as arising in connexion with over-distension of the bladder or obstruction to the escape of urine from it. These are of small size, not usually exceeding a pigeon's egg. They arise, as already described, in the bladders of elderly men who have suffered from severe mechanical obstacle to the passage of the urine, in the shape of stricture or enlarged prostate; they are associated with a generally thickened fasciculated state of the organ, and appear to be the result of pressure on the contained urine during efforts at expulsion, causing extrusion of the mucous and serous coats, and perhaps of the thinned muscular coat at some points of least resistance.

Sacs connected with the bladder are, however, occasionally met with, the origin of which can hardly be explained in this way. These may be single or multiple, and may attain an enormous size. The largest I have seen occurred in a man 35 years of age, otherwise perfectly healthy. There was a tense elastic tumour, smooth and rounded, occupying the whole abdomen and extending into the pelvis, so as to be felt through the rectum. Had it occurred in a woman, the disease would probably have been pronounced to be ovarian. The tumour had existed for six months, had gradually increased, but occasioned no uneasiness except by its pressure-effects. There had been no difficulty in passing urine or in defæcation. The tumour was aspirated at its most prominent part, and seven pints of clear urine were drawn off. The patient suddenly became faint, and died of syncope. On examination after death, two enormous sacs were found connected with the bladder, one on each side, by a rounded opening that would admit the little finger. These orifices were equidistant from the mesial line, and about an inch and a half above each ureter. The sacs were thin-walled, composed chiefly of mucous membrane and peritoneum, possibly having scattered muscular fibres in their composition; both were emptied through the bladder by the one puncture. The ureter on each side was adherent to the wall of the sacculus and considerably pressed upon, and as the result of this the pelves of the kidneys were dilated; the pyramidal portion of the kidney was absorbed and the cortex greatly thickened and indurated by chronic interstitial inflammation. The bladder was greatly dilated and hypertrophied, its mucous membrane was opaque and white, and showed no signs of old or recent cystitis. The prostate and urethra were healthy, and no source of mechanical obstruction was detected. The cause of the condition is extremely obscure. There is a similar specimen, but somewhat less marked, in the museum of University College; the sacculus springs from the same spot, which indeed, from comparison with other specimens, seems to be the common point of origin of all sacculi of the bladder which reach any considerable size.

TUMOURS OF THE BLADDER.

SIMPLE TUMOURS.—The most common simple growth is the **Villous Tumour** or **Papilloma**. It consists of delicate branched processes, which, when the growth is immersed in water, float out, so that it somewhat resembles a sea anemone. These may spring from a narrow base forming a peduncu-

lated mass, or spread over a considerable area of the bladder wall. The base from which they arise may be almost level with the surface of the bladder, or may form a fleshy mass of some thickness. Microscopic examination shows that each papilla is composed of a fine capillary loop, surrounded by an extremely delicate connective tissue, in some parts almost homogeneous, with numerous rounded or spindle-shaped cells scattered through it. The surface is covered with epithelium of the same character as that of the bladder, but more delicate. The cells are often oval or fusiform, and are arranged in several layers. This delicate epithelium separates almost immediately if the growth is put in water, and is consequently often lost in microscopic specimens. The base is composed of loose and highly vascular connective tissue. These tumours almost invariably spring from the neighbourhood of the trigone, although rarely from the trigone itself. Hurry

Fenwick found that in 43 per cent. the growth is attached to the orifice of the right ureter, in 26 per cent. to that of the left, and in 10 per cent. to the interureteral region. They are usually single, but occasionally two or more are found. Thompson states that only about one in six or seven is distinctly pedunculated, the great majority being more or less sessile. When pedunculated, the pedicle may, in rare cases, be of considerable length, sometimes an inch or more.

Other simple tumours are occasionally met with. Thus in children **simple mucous polypi** have been observed. They are smooth or nearly smooth on the surface, and composed chiefly of myxomatous tissue, similar to that seen in the simple polypus of the nose. In others the connective tissue basis of the tumour was so firm and the papillation on the surface so imperfect

Fig. 901.—Villous Tumour of Bladder.

that the growth has been described as a **fibroma**. Probably all these growths are closely related to each other, consisting essentially of an outgrowth from the submucous tissue of the bladder. **Myomata** also, or tumours containing non-striated muscular fibre, have been met with springing from the wall of the bladder.

Symptoms.—Simple tumours of the bladder occur usually in youth or early middle age. The earliest symptom in all forms of simple tumour is painless hæmorrhage. At first it is small in amount and intermittent, but as the disease progresses it becomes more abundant and almost constant. The characteristic sign of hæmorrhage from a villous tumour is that the blood is not uniformly mixed with the urine, but comes chiefly towards the end of micturition, sometimes dropping away almost pure after the urine has ceased to flow. The quantity may be very large, and clots are often passed. As the disease advances frequency of micturition and the general signs of irritability of the bladder may make their appearance, but hæmaturia may form the only symptom for many months or even years. I have known abundant hæmaturia to continue for many years—for twelve or fourteen—probably from a papilloma, without deranging the general health to so great an extent as might be

expected from so continuous and copious a loss of blood. The most important sign, and one which should always be persistently sought for, is the passage of recognizable fragments of the growth in the urine. But little information is gained by sounding; occasionally some irregularity may be felt, but its nature and outline cannot be determined. A hollow sound may, however, return with some of the growth in its eye, and thus determine the nature of the case. Profuse hæmorrhage, after sounding, commonly occurs, but is not sufficient to found a diagnosis upon. Examination of the trigone from the rectum never gives any information unless the tumour be very large, when it might possibly be recognized by pressing firmly above the pubes at the same time. Careful examination of the bladder by means of a small flat-bladed lithotrite may detect the presence of the tumour, as in the first case recorded by Thompson.

These tumours occasionally become encrusted with *phosphatic* matter, deposited upon them by the urine, and then they will resemble still more closely a calculus when the bladder is sounded; from it, however, they may be distinguished by their fixed character, and by the impossibility of passing a sound around them.

If the disease be left unrelieved it terminates fatally sooner or later, sometimes by exhaustion from constant loss of blood, but more often by disease of the kidneys induced by the obstruction to the orifices of the ureters by the growth, or by septic inflammation extending to the pelvis of the kidney.

The **Diagnosis** can usually be made by attention to the above points, but it must be remembered that certain other affections may cause symptoms closely resembling those of a benign tumour. Among these Hurry Fenwick, who has made a special study of this subject, enumerates:—1, Certain forms of prostatic congestion occurring in young men; 2, Certain forms of renal hæmorrhage, such as that due to granular kidney (p. 1008) and early carcinoma; 3, Urethral caruncle in the female; and 4, Stone in the bladder, especially in elderly men, if the bladder be insensitive, or the stone lodged behind the prostate. In practised hands the employment of the electric cystoscope has proved of the greatest value in the detection of simple tumours of the bladder, and as a means of distinguishing between this disease and other causes of painless hæmaturia (p. 1135). Not only may the presence of the tumour be ascertained, but valuable information may be gained as to its size and situation.

In the cases in which the Surgeon is unable to make a certain diagnosis by other methods, he may proceed to explore the bladder digitally through an opening, which will also serve for the removal of the growth, if such be found to exist. This exploration may be carried out through a perinæal incision, similar to that recommended by Thompson in some cases of irritable bladder; but, as a general rule, suprapubic cystotomy allows a more thorough examination, and is far more convenient for the removal of the tumour. Should there be no papilloma, the method of examination will determine the condition of the interior of the bladder, the presence or not of malignant disease, or of encysted calculus, and if none of these are present, will serve as an opening through which drainage may be maintained, in the hope of relieving the irritability or chronic inflammation from which the patient is suffering.

In females the bladder is easily explored by dilatation of the urethra and

lated mass, or spread over a considerable area of the bladder wall base from which they arise may be almost level with the surface of the bladder, or may form a fleshy mass of some thickness. Microscopic examination shows that each papilla is composed of a fine capillary loop, surrounded by an extremely delicate connective tissue, in some parts almost homogeneous with numerous rounded or spindle-shaped cells scattered through it. The surface is covered with epithelium of the same character as that of the bladder, but more delicate. The cells are often oval or fusiform, and arranged in several layers. This delicate epithelium separates almost immediately if the growth is put in water, and is consequently often seen in microscopic specimens. The base is composed of loose and highly vascular connective tissue. These tumours almost invariably spring from the neighbourhood of the trigone, although rarely from the trigone itself.

Fenwick found that in 48 per cent. the tumour is attached to the orifice of the right ureter, in 26 per cent. to that of the left, and in 26 per cent. to the interureteral region. They are usually single, but occasionally two or more are found. Thompson states that only about one in six or seven is distinctly pedunculated, the great majority being more or less sessile. If pedunculated, the pedicle may, in rare cases, be of considerable length, sometimes an inch or more.

Other simple tumours are occasionally observed. Thus in children simple mucous polyps have been observed. They are smooth or slightly lobulated on the surface, and composed of myxomatous tissue, similar to that seen in the simple polypus of the nose. In other cases the connective tissue basis of the tumour was well marked, and the papillation on the surface so important.

Fig. 501.—Villous Tumour of Bladder.

that the growth has been described as a *fibroma*. Probably all these growths are closely related to each other, consisting essentially of an outgrowth from the submucous tissue of the bladder. *Myomata* also, or tumours containing non-striated muscular fibre, have been met with springing from the wall of the bladder.

Symptoms.—Simple tumours of the bladder occur usually in youth or early middle age. The earliest symptom in all forms of simple tumour is pain and hæmorrhage. At first it is small in amount and intermittent, but as the disease progresses it becomes more abundant and almost constant. A characteristic sign of hæmorrhage from a villous tumour is that the blood does not uniformly mix with the urine, but comes chiefly towards the end of micturition, sometimes dropping away almost pure after the urine has ceased to flow. The quantity may be very large, and clots are often passed. As the disease advances frequency of micturition and the general signs of irritability of the bladder may make their appearance, but hæmaturia may form the only symptom for many months or even years. I have known abundant hæmaturia continue for many years—for twelve or fourteen—probably from a papilloma, without deranging the general health to so great an extent as might be

introduction of the forefinger, a proceeding which, as a rule, is not even followed by incontinence of urine.

The **Treatment** of simple tumours of the bladder was up to a recent period of the most unsatisfactory character, Surgeons usually contenting themselves with attempting to restrain the hæmorrhage by means of gallic acid and similar astringents. Operative means were seldom employed. It is true that Civiale removed a small growth situated near the neck of the bladder by seizing and twisting it off with a lithotrite. Warner removed a tumour of this kind the size of an egg from the bladder of a woman after dilating the urethra. Billroth removed a tumour from the bladder of a boy which proved to be in parts a myo-sarcoma, in others a myo-carcinoma. It was as large as a man's fist, and had a pedicle which appeared to be connected with the muscular coat. The operation consisted of cystotomy by the ordinary lateral operation. But as the tumour was too large to be got away through the perinæum, the bladder was opened above the pubes by a free transverse cut. The tumour was then torn away by the finger, and the pedicle cut across with a knife guarded by the finger. The patient did well. Humphry in 1877 operated on a boy who had a tumour in the bladder causing dysuria and hæmorrhage. He opened the bladder by lateral cystotomy through the perinæum, and removed the tumour with forceps and the finger-nail. It proved to be a fibro-sarcoma. The patient made a good recovery. Volkmann and Marcacci both performed suprapubic cystotomy for the removal of vesical myomata, but with fatal results. In 1881 Ransohoff of Ohio removed a tumour as large as a small peach growing from the posterior wall of the bladder. The operation he practised was lateral cystotomy; the tumour was then scraped away by means of one of Volkmann's sharp spoons. The patient recovered after a tedious convalescence.

To Thompson is due the merit of having placed the operation on a more definite basis. His earlier operations were all performed through the perinæal incision, described at p. 1119. The finger was introduced into the bladder through the opening in the membranous urethra, and the position of the tumour ascertained; it was then crushed or torn away from the mucous membrane by means of specially-constructed forceps. Increasing experience showed that this method was only adapted to simple pedunculated growths of very moderate size. For large growths, therefore, Thompson found it necessary to proceed to suprapubic cystotomy, pushing up the bladder with a large sound passed through the perinæal wound.

More recently, however, Thompson has practised suprapubic cystotomy both for exploration and removal of the growth. Even for small pedunculated growths this operation is probably safer, especially for those Surgeons whose experience is limited, as in it the forceps can be guided by sight and touch, whereas, by the perinæal method, it is more or less a scratch in the dark. Among others who have especially advocated the high operation are S. Jones Bennett May, and Hurry Fenwick in this country, and Von Bergmann, Guyon, Dittel, and others on the Continent.

Operation.—The bladder is opened in the same way as in the high operation for stone (p. 1043). Each side of the incision in the bladder must be held well up by a stitch passed through the coats. The cavity must then be gently cleaned, either with a small piece of sponge, or by running a stream of boric lotion through it. Great gentleness must be used in doing this, as if

the tumour be made to bleed it is practically impossible to see anything. If, however, the bladder can be cleaned without hæmorrhage, its cavity may be illuminated by means of a lamp and mirror, or, better still, by a small incandescent electric lamp passed into it. Often, however, the blood obscures everything, and the Surgeon must be guided by feeling the growth.

Hurry Fenwick employs a specially-constructed expanding speculum, which is introduced into the opening and passed down to the growth; the water is then sucked out of it, and thus, by means of a strong light, the removal of the growth can be safely carried out. Fergusson's specula, of different sizes, may be used for the same purpose.

The growth is removed with Thompson's forceps, but sometimes, if it is sessile and widely-diffused, it may be scraped away with a sharp spoon. If the bleeding is severe, it may be arrested by sponge pressure, or by cold or hot water, or the galvano-cantery may be applied to the bleeding surface. Strong chemical styptics should be avoided, as they may cause serious cystitis. The after-treatment is the same as in suprapubic lithotomy.

In the female, dilatation of the urethra is so simple a proceeding that it should always be done before any further operation is undertaken.

MALIGNANT TUMOURS.—**Sarcoma** of the bladder is much less common than either papilloma or carcinoma. Roger Williams found that of 90 cases of tumour of the bladder consecutively treated in four London hospitals only 6 were sarcoma, whilst 59 were carcinoma and 23 papilloma. The growth is composed of round cells, or mixed round and spindle cells, and is papillary on the surface. The distinction between this and a papilloma with a thick base which has been inflamed is not easy to make out, and further investigation is required before a clear separation can be made between these tumours; more especially as all new growths in the bladder, whether simple or malignant, tend to assume a papillary form. From a study of fifty cases of sarcoma of the bladder, Fenwick finds that in 20 per cent. the surface of the tumour is villous. Thompson describes tumours which, in his opinion, occupy a place between papilloma and sarcoma, and which he terms "transitional." One tumour removed by him was found to be a chondrifying sarcoma.

Fig. 902.—Carcinoma of Bladder.

Carcinoma appears to be the most common form of new growth affecting the bladder primarily, and, in addition, the bladder is often invaded by malignant growths originating in the rectum or uterus. Primary carcinoma of the bladder assumes the squamous-celled form. Scirrhus is said to have been met with, but most probably it commenced in the prostate and not in the bladder itself. Carcinoma of the bladder often commences on the posterior surface, extending secondarily to the trigone. As a rule the tumour invades the wall of the bladder from the first, and rapidly ulcerates; in rarer instances the tumour grows more superficially, and may slowly form a considerable mass of growth with but little tendency to infiltration in the early stages. The ulcerating surface of the tumour occasionally becomes encrusted with phos-

phatic deposit, and sometimes a phosphatic calculus may form in the diseased bladder, and thus add greatly to the intense pain that usually attends this affection.

Symptoms.—Sarcoma of the bladder is so rare that in speaking of the symptoms of malignant tumours the remarks will have reference chiefly to carcinoma. Sarcoma has been met with in childhood; it is then usually of rapid growth, and quickly proves fatal. Carcinoma is rarely met with before forty, and is more common in men than in women. The symptoms it gives rise to are intense dysuria, with discharge of blood and viscid mucus, in which fragments of the tumour may be found. No conclusion of any kind can be drawn from single cells; it is only when a distinct group of cells is found, possibly attached to a portion of stroma, that any opinion can be formed as to their source. In a case under the care of Berkeley Hill, the nest-like arrangement of the epithelial cells was recognized in some fragments passed in the urine. Thompson states that the diagnosis of cancer from simple tumours may be made by the age of the patient, and by the fact that pain and frequency of micturition appear early, often before the blood. In simple tumours, blood is the first symptom, preceding pain, often by many months. The rapid progress of the disease, and the intensity of the patient's sufferings, usually differ widely from the slow progress and slight discomfort caused by simple tumours during the early period of their development. The symptoms will, however, be found to differ according to the varying tendency of the tumour to infiltrate the wall of the bladder. Fenwick has shown that in the case of the more superficial slowly-growing varieties of carcinoma the early symptoms may closely resemble those of a papilloma; the bleeding being unaccompanied by pain, but usually being more profuse than that due to a simple growth. Cancer of the bladder frequently causes a tumour which can be felt from the rectum: simple tumours practically never do, and for this reason Thompson lays down the law that if the tumour can be felt from the rectum it is not a case to operate on except for the purpose of relieving suffering by perinæal drainage. Death usually occurs from exhaustion and the spread of septic inflammation to the kidneys.

When secondary to rectal cancer, a communication will usually have been established between the two cavities, through which flatus and fæces pass into the bladder, and thus greatly aggravate the patient's sufferings.

The **Treatment** of cancer of the bladder must necessarily be merely palliative in all but exceptional cases. Morphia hypodermically administered, the frequent use of antiseptic injections, possibly drainage of the bladder through a median perinæal section, and, in those cases that are secondary to rectal cancer, colotomy, constitute the main elements of the treatment. In some cases of superficial papillary carcinoma long freedom from recurrence has followed operation; the surface of the growth being removed with forceps and the base with scissors or a lance-pointed knife. The possibility of removing a portion of the wall of the bladder has been demonstrated by numerous experiments on animals, and by operations on the human subject. In 1885 Sonnenburg, of Berlin, removed two-thirds of the bladder wall, opening the peritoneum in so doing. He sutured the peritoneum accurately, but was unable to close the walls of the bladder, and yet the woman survived one month, dying of exhaustion. In the same year, Antal, of Buda Pesth, successfully removed about one-third of the bladder without wounding the peritoneum.

which had to be stripped off part of the portion removed. Such proceedings can, however, rarely be possible.

The **Results** of operation in carefully selected cases of tumour of the bladder have been on the whole satisfactory. Hurry Fenwick has recorded the results of his first 40 operations undertaken for the removal of tumours of the bladder diagnosed to be present by means of the cystoscope. In one case no actual tumour was found, and in another no attempt was made to remove it. In 38 cases a tumour was removed. In 3 cases death was directly due to the operation; in 2 cases of carcinoma recurrence occurred within three months and proved fatal, and in 4 cases a second operation was performed for recurrence. The remaining 27 cases were in good health when the report was made, in one case four years having elapsed since the operation.

HÆMATURIA.

The admixture of blood with the urine may usually be recognized by the colour which it communicates to this fluid. If the blood be in large quantity, the urine will be dark brown, chocolate, or maroon-coloured, and will stain red the bottom of the utensil or a piece of white blotting-paper. If it be in smaller quantity, the urine will be brown in varying shades—smoky, or having something of the aspect of thin beef-tea; in other cases it will be little discoloured, but will deposit a red or brown sediment on standing. Under the microscope, blood-discs may be detected in large numbers. Heat coagulates the blood into a brownish-grey deposit, leaving a clear supernatant fluid. Microscopic examination should never be neglected in doubtful cases, as by that means small traces of blood may be certainly recognized; and, moreover, it must be remembered that in the condition known as hæmatinuria the urine is darkly stained with blood-pigment, but contains no corpuscles. The patient's word that he has passed blood should never be relied upon too implicitly, as high-coloured urine depositing uric acid or urates is often ignorantly supposed to contain blood.

Hæmaturia may arise from a *constitutional* condition or from a *local* cause. When *constitutional*, it may be the consequence of scurvy or purpura. In these cases it will necessarily be associated with other, and probably marked, evidences of the disease. A form of hæmaturia, depending on the presence of a parasite—the *Bilharzia hæmatobia*—is prevalent in Africa, and has been ably investigated by Leuckart, John Harley, Cobbold, and others.

When arising from *local* causes, hæmaturia is a symptom of disease existing in some part of the urinary apparatus, and it often assumes great importance from the loss of blood induced.

Sources.—Hæmaturia may arise from, 1, the Kidneys; 2, the Bladder; 3, the Prostate; or 4, the Urethra.

1. **Hæmorrhage from the Kidneys.**—When occurring from the kidneys, the bleeding may be the result of injury, congestion, acute inflammation, or malignant disease of those organs; of acute, tuberculous, or calculous pyelitis; or of passage of a calculus down the ureter. The most certain evidence that the blood comes from the kidney is the presence of blood-casts of the renal tubules. The renal congestion may be inflammatory or passive; in either case the urine will present, after the discharge of blood has ceased, evidences of chronic renal disease in the form of albumen, pus, or casts. When the hæmorrhage arises from renal calculus the symptoms described at p. 1007 will be v

marked. Blood from the kidney does not often appear as clots, and is uniformly mixed with the urine. Blood-casts of the ureter have been seen in cases of very profuse renal hæmorrhage from cancer or injury.

2. Hæmorrhage from the Bladder.—If the blood proceed from the bladder, it may be the result of congestion of the mucous membrane, of the irritation of a calculus, of a papilloma or other villous tumour, or of the ulceration of malignant disease. When it depends on vesical congestion, there will be a sensation of weight in the region of the bladder, with frequent desire to pass urine; when it depends on calculus, the special symptoms of the existence of stone will be present. When it occurs from a villous tumour at the neck of the bladder, the quantity of blood lost is usually very great and the hæmorrhage persistent. If it arise from malignant disease, the discharge of pus, and of the *débris* of the ulcerating tumour, may afford evidence of the source of the hæmorrhage. Blood from the bladder usually is most abundant towards the end of micturition, especially in cases of tumour, the first urine that passes, or that is drawn off by a catheter, being pale and less bloody than the last, and at the termination nothing but blood may flow. In stone and cystitis it is more often uniformly mixed with the urine. Irregular masses of clot are often passed when the hæmorrhage has been very abundant.

3. Hæmorrhage from the Prostate.—If the prostate be the source of hæmorrhage, the discharge may be occasioned by congestion of that organ, or by its ulceration, simple or malignant. In these cases, exploration by the rectum and urethra will indicate the true cause of the bleeding. The blood usually finds its way back into the bladder rather than towards the penile urethra, and thus may appear towards the end of micturition, or be uniformly mixed with the urine.

4. Hæmorrhage from the Urethra.—The bleeding may arise from congestion or inflammation of the mucous membrane, or may follow rupture of the walls of the canal, consequent on injury or on the introduction of instruments. Blood from the urethra usually flows independently of micturition, as in recent injuries, or passes with the first few drops of urine. It may, however, occasionally come with the last drops expelled. This is by no means uncommon in gonorrhœa, or in cases of gleet dependent upon a granular condition of the mucous membrane of the bulbous portion of the urethra. It seems, then, to be due to the contraction of the ejaculator urinæ squeezing a drop or two of blood from the inflamed spot.

The Treatment of hæmaturia must necessarily have reference to its cause. When it depends on a morbid constitutional state, as scurvy or malarial poisoning, the treatment of the disease, of which the hæmaturia is merely a symptom or an effect, must be conducted on ordinary medical principles. If it arise from inflammatory congestion of the kidneys, bladder, or prostate, cupping, or the application of leeches over the affected part, demulcents, and saline drinks, will be most efficacious; if from passive congestion, saline purgatives, followed by the use of astringents, will speedily induce a cessation of the hæmorrhage. The astringent that exercises the most marked influence in arresting hæmaturia, when that condition is purely passive, is undoubtedly gallic acid. This may be given in five or ten-grain doses, frequently repeated, in infusion of buchu or uva ursi.

Sometimes the bladder becomes distended by a large soft coagulum, filling up its interior, and causing it to reach to the umbilicus, forming a rounded solid tumour, like the gravid uterus. In such circumstances, the largest catheter

that can be introduced must be passed, and an aspirator or lithotrity evacuator adapted to it. By this means the blood, even when coagulated into a single large clot filling the whole bladder, may easily be removed. If these instruments be not at hand, the fluid contents of the bladder must be drawn off by a large catheter, and the more solid portions broken down and washed away by the injection of one of the antiseptic solutions recommended for cleaning the bladder in chronic cystitis (p. 1116). Should decomposition occur, the bladder must be washed out frequently with antiseptic fluids.

CHAPTER LXX.

DISEASES OF THE PROSTATE.

THE prostate is subject to Acute and Chronic Inflammation, to Hypertrophy, and occasionally to Atrophy, Malignant Disease, Tubercle, and the formation of Calculi.

PROSTATITIS.

Acute Inflammation of the Prostate, or Prostatitis, very rarely occurs as an idiopathic affection. When met with, it is usually the result of gonorrhœa, or of the use of instruments, more especially in middle-aged men.

The **Symptoms** are, deeply-seated dull pain, with heat and weight in the perinæum, a frequent desire to pass urine, and very great and spasmodic pain accompanying the act; in fact, the irritability of the neck of the bladder is perhaps the most distressing feature in the disease. These symptoms are, however, common to various inflammatory affections of the urinary organs, and they can be distinctly referred to the inflamed prostate only by rectal exploration. On introducing the finger into the gut, the prostate will be found much enlarged and exquisitely tender. The patient often suffers considerably from the pressure of the inflamed organ upon the rectum during defæcation.

The **Treatment** should be directed to the prevention of suppuration. The perinæum must be well leeches; warm hip-baths and poppy fomentations assiduously employed; and salines administered. In this way, the formation of abscess within or around the prostate may, in many cases, be prevented. Morphia suppositories may be used to relieve pain.

Prostatic Abscess may form as a consequence of acute inflammation, and in this way it is not very unfrequently a complication of gonorrhœa; or it may occur with comparatively little antecedent inflammation—as sometimes happens in pyæmia, or if the organ be accidentally bruised during lithotrity. In these cases, abscess perhaps as frequently forms in the areolar envelope as in the organ itself. Idiopathic suppuration of the prostate, irrespective of any of the above causes, is of rare occurrence; but it may occur in individuals of broken health, the matter then usually accumulating in large quantity, and discharging itself into the bladder.

Symptoms.—When inflammation of the prostate terminates in abscess, rigors, with strangury, and perhaps retention of urine, occur. In many cases the perinæum becomes brawny; in others, tenderness of the gland and deep fluctuation may be felt through the rectum. When left to itself, the abscess most usually gives way into the urethra or neck of the bladder; but it may, especially when occurring in the prostatic capsule, open externally into the perinæum, or even into the rectum. In many cases, the abscess presenting on the urethral surface of the prostate is burst during the introduction of the

catheter, used for the relief of retention of urine caused by the swelling ; the matter escaping along the side of and through the instrument.

Treatment.—It not unfrequently happens that the first certain indication afforded to the Surgeon of the formation of a prostatic abscess is the escape of pus by the urethra, or mixed with the urine, so as to give this fluid a thick milky appearance. In such circumstances, the only available treatment is that for the relief of the strangury and local vesical irritation already described. But if, as sometimes happens, the pus come forward into the perinæum, and a hard brawny mass be felt, a deep incision should be made into this. The Surgeon must not wait for fluctuation, but must cut deeply in the direction of the matter, keeping, however, as nearly as possible in the middle line, with the back of the knife towards the rectum. Even if no pus escape at first, it may do so if the part be well fomented for a few hours ; and thus communication with the urethra or rectum may be prevented. It is rarely necessary to open the abscess into the rectum, but this may be unavoidable if the abscess appears to be on the point of bursting through the mucous membrane. The bowels must first be thoroughly opened, and the rectum cleared with an enema. The patient is then anæsthetized and placed in the lithotomy position, the pelvis being well raised on a pillow. A duck-bill speculum is next passed, and the fluctuating spot incised with a scalpel ; the opening is then dilated with a pair of polypus-forceps, and a drainage-tube inserted. The tube falls out in a few hours, and need not be replaced, as the cavity usually closes rapidly as soon as the pus is let out. If the incision be limited, and kept as nearly as possible in the middle line, there is no hæmorrhage of any consequence.

Retention of Urine from Prostatitis may be due to swelling of the gland, to infiltration of exudation-matter around it, or to the formation of pus in it. If the symptoms are not urgent a morphia suppository should be administered, and the patient should try to pass water in a hot hip-bath. If that fails an instrument must be passed. A soft india-rubber catheter should first be tried. If that fails a soft elbowed catheter not smaller than No. 8 (English scale) should be tried. If soft instruments fail the Surgeon must fall back on silver catheters. In these cases the neck of the bladder may be carried to a considerable distance from the surface, and may then not be reached by an ordinary catheter, which may be buried up to the rings and yet not enter the cavity of that organ. In these circumstances a silver prostatic catheter should be employed ; and this must be carefully introduced, lest, by entering the cavity of an abscess which has already burst *per urethram*, it might be supposed to have entered the bladder itself. In introducing the instrument, care should be taken to keep its point constantly in contact with the upper surface of the urethra, and to hook it round the pubes. The *upper* surface of the urethra is a sure guide to the bladder ; for any abscess, false passage, or irregularity of direction will always first affect the lower aspect of this canal, being surrounded by yielding structures ; whilst the upper part, being firmly supported by bone and ligament, cannot so readily alter its direction.

Chronic Inflammation of the Prostate may follow the acute affection, especially when it is gonorrhœal. It may also be induced by masturbation and other forms of erotic excitement. The patient is troubled by a sense of weight and fulness in the perinæum, and there may be an occasional glairy

discharge from the urethra; fine threads of mucus, the so-called "*prostatic threads*," may often be seen floating in the urine, especially in that first passed, and in the last few drops expelled by straining if these be collected separately. The discharge of glairy mucus from the urethra after micturition or defæcation may be so marked as to constitute a true "*prostatorrhœa*" which is of importance chiefly from its liability to be confounded with spermatorrhœa, and from the depressing effect consequently produced upon the patient's mind. Frequency of micturition and some pain during and after the act may be present. Constipation is almost invariable. Examination by the rectum shows that the prostate is slightly tender, hard, and enlarged, sometimes more on one side than the other. A chronic abscess may slowly form without great increase in the intensity of the symptoms. This complication, which is fortunately rare, is recognized by examination from the rectum. Should the abscess burst into the urethra, the cavity in the indurated gland tissue may be very slow in healing. I have known a case in which, after many years, the prostate remained hard and enlarged, and on pressing firmly on it from the rectum, pus could be made to flow from the urethra. The patient was obliged to draw off his water with a catheter, but suffered very little in his general health.

The **Diagnosis** of this condition from tuberculous disease is often extremely difficult. Its extremely chronic nature, the absence of any disease of the testicles or vesiculæ seminales, the more uniform enlargement of the gland, and the history of the case will usually determine its nature. The distinction between prostatorrhœa and spermatorrhœa may be made by microscopic examination of the discharges.

The **Treatment** consists in attention to the general health. Tonics, especially iron and nux vomica, and aperients are usually required. Moderate exercise, change of air, and sea-bathing may be of use. Locally, the application of cold has proved most useful. The cold sitz bath or perinæal douche may be prescribed once or twice a day. Berkeley Hill advised that the bath should be commenced at a temperature of 50° F. and gradually prolonged and lowered in temperature until ten minutes at 35° F. is reached.

Small rectal injections of cold water may also be used. A belladonna suppository sometimes relieves the uncomfortable sensations. Blistering the perinæum is a recognized method of treatment, but often fails. In obstinate cases in which simpler means have failed injections of nitrate of silver may be made into the prostatic urethra. Berkeley Hill, who regarded this treatment highly, advised that the injection should be made with a Guyon's catheter and syringe, the strength of the solution at the first application being not more than 5 or 10 grains to the ounce and the amount not more than 10 to 20 minims. Ten minims of a 10 per cent. solution of cocaine should be previously injected, and ten minutes after the silver solution has been used the patient is directed to pass his water. If severe pain follows, it may be relieved by a hot hip-bath and belladonna suppositories. Three or four injections are usually required at intervals of one or two weeks, the strength of the solution being increased to 20 or even 50 grains to the ounce. The subsequent passage of a large steel sound may be useful.

In the rare cases in which suppuration occurs, the abscess must be opened in the perinæum.

A deep-seated and very Chronic Abscess sometimes forms in the

pelvis, between the bladder and the rectum, behind the prostate, giving rise to a train of obscure symptoms, indicative of irritation about these organs, such as dysuria, strangury, and occasional admixture of pus with the urine. On careful examination of the perinæum and rectum, some slight hardness may perhaps be deeply felt in the mesial line, or towards one side of it. This slowly increases, and a perinæal abscess of an ill-defined character develops. When this has become sufficiently evident, a free incision should be made into it, and on careful exploration of the cavity with a probe, a sinus will probably be found leading into the pelvis, and to the original seat of the abscess. This requires to be opened up by a free incision on one side or other of the perinæum, as if for lateral lithotomy, and a direct exit given to the matter. The cavity must then be allowed to granulate from the bottom.

CHRONIC ENLARGEMENT OF THE PROSTATE.

Chronic Enlargement of the Prostate may be looked upon as a senile disease, seldom occurring before the age of fifty-five, but commonly met with after this. At that period of life, as Brodie observes, when the hair becomes grey and scanty, when the coats of the arteries begin to become atheromatous, and when the arcus senilis forms on the cornea, the prostate often becomes increased in size; but unless the enlargement interferes with the free escape of the urine, no disease can properly be said to exist. If we look upon the diseased enlargement of the prostate as such an amount of hypertrophy of this organ as interferes seriously with the discharge of the urine, we shall probably not find it so frequent even in old men as is generally supposed. Guthrie states that it is not commonly found in the pensioners at Greenwich Hospital. Thompson found that an enlargement appreciable after death existed in 34 per cent. of men above the age of sixty; but that such a degree of enlargement as to give rise to symptoms during life was met with only in 15 or 16 per cent. of the cases he examined. Though age must be looked upon as the primary cause of hypertrophy of the prostate, there can be little doubt that it may be predisposed to by any continued source of irritation of the urinary organs, such as gonorrhœa, stricture, or hard living. •

Characters.—Enlargement of the prostate is due to hypertrophy of its normal structures—muscular, fibrous, and glandular. In the early stages the enlargement appears to be due chiefly to overgrowth of the glandular tissue, but in the later stages the fibrous tissue is in great excess; when, however, the size of the gland has been very slowly and not greatly enlarged, there is nearly equal hypertrophy of all the tissues. The enlargement generally occupies the whole of the organ, and may cause its size to increase to that of a hen's egg or a small orange. In most cases, all the lobes are enlarged equally or nearly so, but sometimes there is a disproportionate development of one of the lateral lobes or of the middle portion. More rarely, the lateral lobes or the anterior commissure alone are affected.

The enlarged prostate, in the earlier stages, presents to the naked eye an appearance of rotundity and increased fulness; at a more advanced stage, there may be great irregularity of outline. There is usually no change of colour externally, and the texture of the gland is generally indurated; though sometimes, when the glandular element is chiefly increased, it is found to be looser

and softer than natural. On making a section, the cut surface bulges above the level; and the shades of colour are more strongly marked than in the healthy prostate. Not uncommonly, single gland-lobules are found hypertrophied; and in some cases, spheroidal prominences are seen, which are easily enucleated. In some instances, an abundance of fluid escapes from the cut surface and from the openings of the prostatic ducts; while in other cases this is entirely wanting. Small cavities, due to dilatation of the gland-follicles, are occasionally found; sometimes empty, sometimes containing a yellow fluid resembling pus in appearance, but consisting of the prostatic secretion in a thickened state. The prostate may attain a very large size. The largest that I have seen is one in the Norwich Hospital Museum, taken from a man of eighty; it weighs more than 20 ounces.

Simple Prostatic Tumours.—The nature of simple tumours of the prostate has been carefully studied by Thompson; to whose work on the diseases of this organ the student is referred for further information. According to Thompson, tumours of non-malignant character are met with in most cases of hypertrophied prostate, and also occasionally when there is no enlargement of the organ. He divides them into two classes:

“1. Tumours which are generally imbedded in the substance of the prostate, but the structures of which are isolated from those which surround them.

“2. Outgrowths which are continuous in structure with the parts of the prostate whence they spring, but which manifest a tendency to become partially isolated, by assuming a more or less polypoid form, and maintaining attachment to the parent organ through the medium of a pedicle only.”

1. The *isolated tumours* in the substance of the prostate may occupy any portion of the organ; but are, perhaps, more numerous in the lateral lobes than elsewhere. They are easily enucleated, having but a loose connexion with the substance of the gland. In diameter they vary from $\frac{1}{10}$ th to $\frac{1}{2}$ ths of an inch. They are firmer and mostly paler in colour than the proper prostatic tissue, and are less vascular.

“The basis of the tumours appears to be the fibrous basis or stroma of the prostate itself, an admixture of unstriped, soft, pale muscular fibres, and connective with a little elastic tissue, closely interwoven. Interspersed with this, there are present in most cases small cavities containing flattened polygonal or spheroidal epithelium, like that seen in a pouch at the extremity of a prostatic gland-duct, and sometimes, also, some prismatic epithelium. These cavities are sometimes solitary, sometimes slightly branched, and sometimes of an elongated or tubular form. In a few instances there is very little, or perhaps no such glandular tissue to be found; generally, however, a careful search will discover it. In some of the outlying tumours the glandular structure is more perfectly developed—in some it is quite so—and a duct is furnished which evidently carries secretion to the appointed destination.”

2. The part of the prostate which is most usually the seat of *outgrowth* is the middle or urethral portion, which may become greatly enlarged in size, with or without hypertrophy of the lateral lobes. The growth assumes a pyriform shape, and is more or less pedunculated. It is continuous in structure with the prostatic tissues, and has its own duct, which opens into the urethra through the pedicle. Prostatic concretions are commonly found in these outgrowths; never in the isolated tumours.

Though most common in the middle portion of the prostate, outgrowths

may occur from the posterior part of one of the lateral lobes, or from that portion of the gland which lies above or in front of the inner orifice of the urethra.

In rare instances, the verumontanum alone appears to be affected, forming a thickened polypoid outgrowth, which projects in a valvular manner, and interferes materially with the flow of urine.

Thompson points out that, as had been suggested by Velpeau, remarkable analogies exist between these prostatic outgrowths and the fibroid tumours of the uterus. This view is in accordance with the theory that the prostatic utricle is the analogue of the uterus.

Mechanical Effects of Enlarged Prostate on the Urinary Organs.—

Enlargements of the prostate are productive of inconvenience with regard to the flow of urine, giving rise either to retention or to incontinence, or to a kind of mixture of both conditions. When the lateral lobes are enlarged, there is a diminution of the lateral or transverse diameter of the urethra, at the same time that the antero-posterior diameter is increased, so that the canal becomes a chink-like passage. The urethra also becomes greatly elongated and tortuous; and is diverted from the natural direction—this varying with the form of enlargement. When the median portion is enlarged, there is a more or less angular curvature of the canal at the prostatic point. When, in addition, there is enlargement of one lateral lobe, the urethra is curved also laterally in the direction of the enlarged lobe. The lateral deviation may occur also when there is enlargement of the middle lobe; but it then affects both sides.

Fig. 903.—Bladder laid open, showing Enlargement of Urethral Portion of Prostate.

The inner orifice of the urethra also undergoes changes. Enlargement of the posterior part of the middle portion of the prostate gives it a crescentic form, with the convexity directed upwards; and, in enlargement of either lateral lobe, the convexity of the crescent lies towards the side opposite the enlarged lobe. Sometimes, when there are two or more irregularly enlarged lobes, the orifice is very much distorted, elongated, and tortuous. In cases of valvular or pedunculated projections from the posterior portions, the orifice may appear to be overlapped altogether. This condition existed in the case from which the accompanying drawing (Fig. 903) was taken; the third, or median lobe forming a pedunculated tumour which acted like a valve and obstructed the exit of the urine from the bladder, though it did not offer any obstacle to the introduction of a catheter.

The elongation and expansion of the prostatic portion of the urethra give rise to an increase in its capacity, so that it sometimes holds two or three ounces of urine; and the elongation will carry the neck of the bladder upwards and behind the pubes, to a considerable distance from its normal position.

While the lateral enlargements cause the urethra to assume a somewhat tortuous course, the middle lobe, if hypertrophied, may readily occasion retention,

by projecting against the entrance to this winding channel, and falling over it like a valve whenever the patient attempts to pass urine, as in Fig. 904. In this condition no urine is passed until by accumulation within the bladder the neck has become so stretched that the valve-like obstruction no longer closes the orifice. Then a small quantity of urine is expelled; the neck of the bladder collapses, and before the cavity is completely emptied, the orifice is blocked by the projecting middle lobe, and the flow ceases. Thus a certain amount of urine is always retained, which is commonly termed the "residual urine,"

and none escapes till the bladder is in a state of considerable tension. As the middle lobe increases in size, a greater degree of stretching is necessary before urine can escape. Under this constant tension the bladder slowly yields and becomes dilated, its walls are thickened by fibroid tissue, and it gradually becomes completely "atonic," losing all active power of contraction. At last a condition is reached in which urine flows only when the bladder is greatly distended, and the escape of a few drops is sufficient to render the obstruction complete, and thus a condition of almost constant dribbling is established. This forms the most typical variety of prostatic obstruction. Less commonly, the obstacle to the passage of urine is of such a nature that it can be forced by increased pressure, and we then find the muscular coat of the bladder hypertrophied, as in stricture of the urethra. In still more rare cases the middle lobe lies between the enlarged lateral lobes, thus propping the neck of the bladder open, and then true incontinence may occur with constant dribbling of urine.

Fig. 904.—Results of enlarged Prostate: Bladder enlarged; Ureters dilated, Chronic Disease of Kidneys.

The effect on the kidney will vary according to circumstances. If the bladder is in a constant state of over-distension, a similar increased tension will occur in the ureters, as it is evident that increased force will be required to drive the urine through their orifices. We consequently find all the signs of increased tension already described (p. 994); dilated ureters and pelves, absorption of the pyramids, chronic interstitial nephritis, &c. (Fig. 904). Finally, should decomposition occur in the urine retained in the bladder, it may extend through the orifice of the ureter to the kidney; and in this way a large proportion of patients suffering from prostatic disease die of septic suppurative nephritis.

Moral Effects of Enlarged Prostate.—The irritation of a congested and enlarged prostate will excite libidinous ideas in the aged, which may lead to the perpetration of acts of indecency—such as exposure of the person, indecent assaults on children, or to a general deterioration of the moral tone.

But not only does the diseased state of this body thus excite a depraved condition of the mind; the converse also will happen. And if the true history of many cases of prostatic congestion and hæmorrhage were told, the diseases would be found to have begun in irregular sexual or erotic excitement by which the genital organs have been over-stimulated.

Bar at the Neck of the Bladder.—Under this name has been described a transverse ridge obstructing the internal orifice of the urethra, and causing symptoms exactly analogous to those produced by hypertrophy of the middle portion of the prostate. According to Thompson, the fold is in the great majority of cases actually caused by an outgrowth from the middle portion of the gland. In exceptional cases, however, it may be due to hypertrophy of the muscular fibres at the neck of the bladder, produced by long continued irritation, usually caused by chronic cystitis from stone or stricture. Lastly, in very rare cases, a valve-like fold of mucons membrane may be drawn up by enlargement of the lateral lobes without affection of the median portion of the gland.

The **Symptoms of Enlarged Prostate** arise primarily from the mechanical obstacle offered to the escape of the urine. The first symptoms usually consist in the feeling of a necessity to strain slightly before the urine will flow; and then, after the bladder has apparently been emptied, in the involuntary escape of a small quantity of urine. The patient also finds that he is much longer than usual in emptying the bladder; for though the stream flows freely enough as soon as it has once begun to escape, yet it cannot be properly projected, the bladder having, to a certain extent, lost its tonicity. It commonly happens that the more the patient strains the less readily will the urine come away, whereas when he remains quiet, it will usually flow with more freedom. This is especially the case in pedunculated enlargements of the middle lobe. About this time frequency of micturition usually becomes a marked feature, especially at night. In fact, the great majority of patients apply to the Surgeon, not on account of difficulty in passing water, but because they are called upon to perform the act of micturition too frequently. This condition may gradually increase till it amounts to actual dribbling. The frequent discharge of a small quantity of urine may lead the incautious Surgeon to suppose that the patient is affected with true incontinence of urine or with irritability of the bladder. This error may always be guarded against by careful examination of the pubic region by percussion and palpation. Dulness will often be found extending half-way to the umbilicus, and the tense distended bladder may be readily felt above the pubes. If there is any doubt the patient must be made to pass water, and immediately afterwards a soft catheter must be passed. In this way the presence of residual urine and its quantity are determined.

The symptoms may for a long time remain limited to frequency of micturition with some difficulty in the act. The urine remains acid and normal in every respect, and the patient suffers but little, if at all, in his general health. The condition is, however, always one of considerable danger. The over-distended bladder is always prone to slight attacks of cystitis from exposure to cold or other causes. The urine then becomes cloudy from excess of mucus, and often acquires an offensive fishy smell, while still remaining acid. The mucus accumulates in the pouch behind the enlarged prostate, and ammoniacal decomposition readily takes place. This may occur without the passage of

instruments, but in a considerable proportion of cases it is not noticed before the use of the catheter has been commenced. Should it happen, the cystitis becomes more acute, and the symptoms of septic poisoning—febrile disturbance, great depression, brown tongue, nausea, delirium, &c.—may set in and terminate fatally, when septic inflammation of the kidneys, by extension up the ureter, will usually be found to have been the immediate cause of death.

Complete Retention of Urine from Enlarged Prostate is a common complication of the disease. It may arise in a patient who has not been able to empty his bladder for some time, and is little more than an aggravation of his usual condition, or it may occur in an old man whose prostate is considerably enlarged, but who, under ordinary circumstances, gets rid of his urine without difficulty. In the latter case it is due to congestion and swelling of the diseased gland, usually induced by exposure to cold, or by alcoholic or venereal excesses. It is especially apt to occur after drinking the sour bad wines usually provided at public dinners.

Diagnosis.—The exact condition of the enlarged prostate can be ascertained only by examination through the rectum and urethra. By rectal exploration with the finger, the degree of enlargement of the lateral lobes can best be ascertained; though, as in many cases the end of the finger cannot reach the further extremity of the gland, it will be impossible to say to what extent the hypertrophy has extended. The urethral exploration must be conducted by means of a long gum-elastic or a silver prostatic catheter, and will afford information that rectal exploration cannot give; by it are ascertained approximately the size of the middle lobe, and the condition of the urethra as to elongation and curve.

The diagnosis of enlarged prostate has to be made from, 1, Stricture of the Urethra; 2, Calculus of the Bladder; 3, Vesical Tumour; 4, Chronic Cystitis; 5, Atony of the Bladder; 6, Paralysis of the Bladder.

1. In *Stricture* the stream of urine is small, but the jet is increased by straining, while in enlarged prostate the stream is dribbling, but not reduced in volume, and straining only makes matters worse. Stricture most commonly occurs before middle life, prostatic disease always after. In stricture the obstruction is within six inches of the meatus; in prostatic disease it is at least seven from the orifice. It is not wise, however, to trust too implicitly to measurements in inches, as the penis varies considerably in length. If the finger be passed into the rectum, it can at once be determined whether the point of obstruction is in front of the apex of the prostate.

2. *Calculus* presents many symptoms in common with enlarged prostate, and its more special symptoms may be absent. In stone the frequency of micturition is greater by day, in prostatic disease it is worse at night. The presence of a small quantity of florid blood in the urine passed after exercise should make the Surgeon strongly suspect the presence of a stone; but the use of the sound will alone lead to an exact diagnosis.

3. *Vesical Tumour* gives rise to more pain and tenderness on the introduction of instruments than prostatic enlargement; and the urine generally contains blood and mucus, often with sabulous matter. Microscopic examination of the contents of the urine may show the presence of the tissues of the tumour. Malignant tumours may often be felt through the rectum; while villous growths give rise to the almost constant presence of blood in the urine.

4. In *Chronic Cystitis*, without complication, the absence of the physical signs of enlarged prostate, as ascertained by examination by the rectum and urethra, will establish the diagnosis.

5. *Atony of the Bladder* is, as before stated, very commonly associated with enlarged prostate. Its absence would be shown by the urine flowing from the catheter in a steady stream, not influenced by the respiratory movements, indicating an active contraction of the bladder.

6. True *Paralysis* of the bladder, accompanied by a similar affection of other parts, is recognized by its concomitant conditions, and by the absence of physical signs of enlarged prostate, and, as in atony, by the passive nature of the flow of urine through the catheter.

Treatment.—In the treatment of enlarged prostate, little can be done by medical means; though the patient's condition may be somewhat ameliorated by remedies calculated to lessen irritation about the urinary organs, and to improve the condition of the urine. If it be very acid, alkalies with hyoscyamus should be given. If the symptoms of chronic cystitis make their appearance, the various remedies recommended in the treatment of that disease may be given. If hæmorrhage occurs, tincture of perchloride of iron, infusion of uva ursi, or gallic acid, will be useful. Counter-irritation, the application

Fig. 905.—Elbowed Catheter.

of iodine, and other measures intended to promote absorption of the enlarged gland, are not of the slightest service.

In the great majority of cases the sole treatment of enlarged prostate consists in the regular use of the catheter, in order to draw off retained urine; and when once this treatment has been commenced, it must be continued for the remainder of life, the patient being taught to use the instrument for himself. In almost all cases a Jaques's flexible india-rubber catheter can be passed into the bladder. Its use is so perfectly painless and free from danger, that it should always be tried before adopting more severe measures. If from any cause it be necessary to retain such an instrument, Hutchinson uses a nozzle with rings passed into the orifice of the india-rubber catheter, and fitted with a "styletted plug." The nozzle is about three-quarters of an inch in length, and is fitted accurately by the plug. The stylet reaches about two inches down the catheter so as to stiffen it. With such an instrument in use, the patient need not be confined to bed. If the soft rubber catheter will not pass, by far the most convenient instrument in the majority of cases is the soft French "elbowed" catheter—the *cathéter à coude*, of the size and shape here represented (Fig. 905). The stem is soft and pliable, but the angle and eyed point are made of firm gum-catheter material. By keeping the point well up against the urethra, it will often slip in very easily and smoothly in cases of enlarged prostate. These catheters are made with their points bent at different angles or with double elbows, instead of single, and very often when one will not pass, another of a slightly different form will slip in readily.

The size of the instrument is of some importance. As a rule, No. 8 or 9 passes most easily. Nothing is gained by using a smaller instrument, as the passage through the diseased prostate, although it obstructs the flow of urine, is always larger than that through a healthy gland.

If neither of these instruments will enter the bladder, a common French conical instrument may pass; but this very rarely succeeds when the cond catheter fails.

A common gum-elastic catheter of full size, which may be bent to any angle in hot water and fixed by immersing it in cold, may pass when other instruments fail. Sometimes, if it be bent to a curve like that of a lithotrite, it may slip over the enlarged middle lobe. It must be remembered that the heat of the urethra soon causes the catheter to lose the form impressed upon it, and consequently, if it does not enter at once, prolonged attempts to pass it are useless.

Brodie recommended that a gum-elastic instrument, long and of large size,

Fig. 106. — Enlarged Middle Lobe of Prostate, arresting progress of the Catheter.

on a well-curved stylet so that it might preserve its curve when that is withdrawn, should be kept in readiness for these cases. A manœuvre mentioned by Brodie will often be of use in surmounting a large middle lobe: viz., after passing the gum-elastic catheter as far as it will go, to withdraw the stylet slightly, so as to tilt up the point of the catheter, which then slips over the obstacle.

If none of the foregoing means succeed, the Surgeon must have recourse to silver instruments. If the prostate be much enlarged it may be necessary, in order to reach and empty the bladder, to use a prostatic catheter. This instrument should be of large size, about No. 12. In order properly to enter the bladder, which is carried away from the surface by the elongated urethra, the prostatic catheter should be about four inches longer than an ordinary one; and, as the neck of the viscus is usually pushed up high behind the pubes by the projection upwards of the lateral lobes, the curve of the

instrument should be greater and longer than usual. I find the best-shaped prostatic catheter to be one the curve of which is exactly the third of the circumference of a circle five-and-a-half inches in diameter. The eyes should be large and rounded; and I have found it of use to have the lower end of the stylet provided with a piston-plate, so that, by withdrawing this the mucus may be sucked in through the eye of the instrument. In introducing the catheter, care must be taken when the point enters the prostatic urethra to depress the handle well between the thighs, while the instrument is drawn slightly towards the pubes, lest the end hitch against the enlarged middle lobe (Fig 906). If it be simply depressed, without at the same time being held back a little, it will probably tunnel the obstruction. In some cases the ordinary catheter passed in the same way will enter more easily than the prostatic. It is sometimes possible to lift the catheter over the obstruction by pressing on it with the finger in the rectum. In fact, no one curve or one kind of instrument will answer in all cases. If it is necessary to use a rigid instrument, I certainly think a silver instrument is safer and more easily managed than the gum-elastic. It might be supposed that less chance of mischief would result from the gum-elastic than from the metallic catheter, as being the softer and more yielding instrument; but this is erroneous, if the stylet be allowed to remain in, as it is then as rigid at the point, as hard, and as likely to penetrate soft structures as a silver one would be.

The commencement of catheterization in cases of enlarged prostate cannot be regarded as altogether free from risk. The patient is liable to an attack of fever such as may follow the introduction of an instrument for other purposes, and the precautions mentioned at p. 1125 must be carefully observed. Exposure to cold is especially to be avoided after the catheter has been used. Before the instrument is passed, the patient should empty his bladder as completely as possible, in order that the amount of the residual urine may be ascertained. If this be about three or four ounces the bladder should be emptied every morning and evening, whilst if this amount be much exceeded the catheter must be passed three or four times in the twenty-four hours.

The patient should use a soft catheter if possible, and the Surgeon must give careful directions concerning the cleansing of the instrument.

In cases complicated with severe cystitis and great irritability of the bladder which have resisted simpler treatment, drainage of the bladder may be the only means of saving the patient from fatal exhaustion or septic poisoning. This may most readily be done by introducing a tube through an incision into the membranous urethra (p. 1119); or suprapubic cystotomy may be performed, as first practised by Thompson in 1869, the opening being maintained by a gum-elastic catheter fitted with a silver shield, and provided with a rubber bottle to receive the urine. The suprapubic method has the advantage of allowing a thorough investigation of the bladder and prostate, but it is only available if the patient's condition is favourable.

Operative Treatment of Enlarged Prostate.—Various operative procedures have been proposed from time to time for the relief of difficult micturition from enlarged prostate or bar at the neck of the bladder. One of the first of these was Mercier's operation of division of the bar at the neck of the bladder by means of an instrument shaped like a lithotrite, the male blade of which was represented by a concealed knife. Mercier also devised another

discharge from the urethra; fine threads of mucus, the so-called "*prostatic threads*," may often be seen floating in the urine, especially in that first passed, and in the last few drops expelled by straining if these be collected separately. The discharge of glairy mucus from the urethra after micturition or defæcation may be so marked as to constitute a true "*prostatorrhœa*" which is of importance chiefly from its liability to be confounded with spermatorrhœa, and from the depressing effect consequently produced upon the patient's mind. Frequency of micturition and some pain during and after the act may be present. Constipation is almost invariable. Examination by the rectum shows that the prostate is slightly tender, hard, and enlarged, sometimes more on one side than the other. A chronic abscess may slowly form without great increase in the intensity of the symptoms. This complication, which is fortunately rare, is recognized by examination from the rectum. Should the abscess burst into the urethra, the cavity in the indurated gland tissue may be very slow in healing. I have known a case in which, after many years, the prostate remained hard and enlarged, and on pressing firmly on it from the rectum, pus could be made to flow from the urethra. The patient was obliged to draw off his water with a catheter, but suffered very little in his general health.

The **Diagnosis** of this condition from tuberculous disease is often extremely difficult. Its extremely chronic nature, the absence of any disease of the testicles or vesiculæ seminales, the more uniform enlargement of the gland, and the history of the case will usually determine its nature. The distinction between prostatorrhœa and spermatorrhœa may be made by microscopic examination of the discharges.

The **Treatment** consists in attention to the general health. Tonics, especially iron and nux vomica, and aperients are usually required. Moderate exercise, change of air, and sea-bathing may be of use. Locally, the application of cold has proved most useful. The cold sitz bath or perinæal douche may be prescribed once or twice a day. Berkeley Hill advised that the bath should be commenced at a temperature of 50° F. and gradually prolonged and lowered in temperature until ten minutes at 35° F. is reached.

Small rectal injections of cold water may also be used. A belladonna suppository sometimes relieves the uncomfortable sensations. Blistering the perinæum is a recognized method of treatment, but often fails. In obstinate cases in which simpler means have failed injections of nitrate of silver may be made into the prostatic urethra. Berkeley Hill, who regarded this treatment highly, advised that the injection should be made with a Guyon's catheter and syringe, the strength of the solution at the first application being not more than 5 or 10 grains to the ounce and the amount not more than 10 to 20 minims. Ten minims of a 10 per cent. solution of cocaine should be previously injected, and ten minutes after the silver solution has been used the patient is directed to pass his water. If severe pain follows, it may be relieved by a hot hip-bath and belladonna suppositories. Three or four injections are usually required at intervals of one or two weeks, the strength of the solution being increased to 20 or even 50 grains to the ounce. The subsequent passage of a large steel sound may be useful.

In the rare cases in which suppuration occurs, the abscess must be opened in the perinæum.

A deep-seated and very Chronic Abscess sometimes forms in the

pelvis, between the bladder and the rectum, behind the prostate, giving rise to a train of obscure symptoms, indicative of irritation about these organs, such as dysuria, strangury, and occasional admixture of pus with the urine. On careful examination of the perinæum and rectum, some slight hardness may perhaps be deeply felt in the mesial line, or towards one side of it. This slowly increases, and a perinæal abscess of an ill-defined character develops. When this has become sufficiently evident, a free incision should be made into it, and on careful exploration of the cavity with a probe, a sinus will probably be found leading into the pelvis, and to the original seat of the abscess. This requires to be opened up by a free incision on one side or other of the perinæum, as if for lateral lithotomy, and a direct exit given to the matter. The cavity must then be allowed to granulate from the bottom.

CHRONIC ENLARGEMENT OF THE PROSTATE.

Chronic Enlargement of the Prostate may be looked upon as a senile disease, seldom occurring before the age of fifty-five, but commonly met with after this. At that period of life, as Brodie observes, when the hair becomes grey and scanty, when the coats of the arteries begin to become atheromatous, and when the arcus senilis forms on the cornea, the prostate often becomes increased in size; but unless the enlargement interferes with the free escape of the urine, no disease can properly be said to exist. If we look upon the diseased enlargement of the prostate as such an amount of hypertrophy of this organ as interferes seriously with the discharge of the urine, we shall probably not find it so frequent even in old men as is generally supposed. Guthrie states that it is not commonly found in the pensioners at Greenwich Hospital. Thompson found that an enlargement appreciable after death existed in 34 per cent. of men above the age of sixty; but that such a degree of enlargement as to give rise to symptoms during life was met with only in 15 or 16 per cent. of the cases he examined. Though age must be looked upon as the primary cause of hypertrophy of the prostate, there can be little doubt that it may be predisposed to by any continued source of irritation of the urinary organs, such as gonorrhœa, stricture, or hard living. •

Characters.—Enlargement of the prostate is due to hypertrophy of its normal structures—muscular, fibrous, and glandular. In the early stages the enlargement appears to be due chiefly to overgrowth of the glandular tissue, but in the later stages the fibrous tissue is in great excess; when, however, the size of the gland has been very slowly and not greatly enlarged, there is nearly equal hypertrophy of all the tissues. The enlargement generally occupies the whole of the organ, and may cause its size to increase to that of a hen's egg or a small orange. In most cases, all the lobes are enlarged equally or nearly so, but sometimes there is a disproportionate development of one of the lateral lobes or of the middle portion. More rarely, the lateral lobes or the anterior commissure alone are affected.

The enlarged prostate, in the earlier stages, presents to the naked eye an appearance of rotundity and increased fulness; at a more advanced stage, there may be great irregularity of outline. There is usually no change of colour externally, and the texture of the gland is generally indurated; though sometimes, when the glandular element is chiefly increased, it is found to be looser

and softer than natural. (On making a section, the cut surface bulges above the level; and the shades of colour are more strongly marked than in the healthy prostate. Not uncommonly, single gland-lobules are found hypertrophied; and in some cases, spheroidal prominences are seen, which are easily enucleated. In some instances, an abundance of fluid escapes from the cut surface and from the openings of the prostatic ducts; while in other cases this is entirely wanting. Small cavities, due to dilatation of the gland-follicles, are occasionally found; sometimes empty, sometimes containing a yellow fluid resembling pus in appearance, but consisting of the prostatic secretion in a thickened state. The prostate may attain a very large size. The largest that I have seen is one in the Norwich Hospital Museum, taken from a man of eighty; it weighs more than 20 ounces.

Simple Prostatic Tumours.—The nature of simple tumours of the prostate has been carefully studied by Thompson; to whose work on the diseases of this organ the student is referred for further information. According to Thompson, tumours of non-malignant character are met with in most cases of hypertrophied prostate, and also occasionally when there is no enlargement of the organ. He divides them into two classes:

“1. Tumours which are generally imbedded in the substance of the prostate, but the structures of which are isolated from those which surround them.

“2. Outgrowths which are continuous in structure with the parts of the prostate whence they spring, but which manifest a tendency to become partially isolated, by assuming a more or less polypoid form, and maintaining attachment to the parent organ through the medium of a pedicle only.”

1. The *isolated tumours* in the substance of the prostate may occupy any portion of the organ; but are, perhaps, more numerous in the lateral lobes than elsewhere. They are easily enucleated, having but a loose connexion with the substance of the gland. In diameter they vary from $\frac{1}{10}$ th to $\frac{3}{8}$ ths of an inch. They are firmer and mostly paler in colour than the proper prostatic tissue, and are less vascular.

“The basis of the tumours appears to be the fibrous basis or stroma of the prostate itself, an admixture of unstriped, soft, pale muscular fibres, and connective with a little elastic tissue, closely interwoven. Interspersed with this, there are present in most cases small cavities containing flattened polygonal or spheroidal epithelium, like that seen in a pouch at the extremity of a prostatic gland-duct, and sometimes, also, some prismatic epithelium. These cavities are sometimes solitary, sometimes slightly branched, and sometimes of an elongated or tubular form. In a few instances there is very little, or perhaps no such glandular tissue to be found; generally, however, a careful search will discover it. In some of the outlying tumours the glandular structure is more perfectly developed—in some it is quite so—and a duct is furnished which evidently carries secretion to the appointed destination.”

2. The part of the prostate which is most usually the seat of *outgrowth* is the middle or urethral portion, which may become greatly enlarged in size, with or without hypertrophy of the lateral lobes. The growth assumes a pyriform shape, and is more or less pedunculated. It is continuous in structure with the prostatic tissues, and has its own duct, which opens into the urethra through the pedicle. Prostatic concretions are commonly found in these outgrowths; never in the isolated tumours.

Though most common in the middle portion of the prostate, outgrowths

may occur from the posterior part of one of the lateral lobes, or from that portion of the gland which lies above or in front of the inner orifice of the urethra.

In rare instances, the verumontanum alone appears to be affected, forming a thickened polypoid outgrowth, which projects in a valvular manner, and interferes materially with the flow of urine.

Thompson points out that, as had been suggested by Velpeau, remarkable analogies exist between these prostatic outgrowths and the fibroid tumours of the uterus. This view is in accordance with the theory that the prostatic utricle is the analogue of the uterus.

Mechanical Effects of Enlarged Prostate on the Urinary Organs.—

Enlargements of the prostate are productive of inconvenience with regard to the flow of urine, giving rise either to retention or to incontinence, or to a kind of mixture of both conditions. When the lateral lobes are enlarged, there is a diminution of the lateral or transverse diameter of the urethra, at the same time that the antero-posterior diameter is increased, so that the canal becomes a chink-like passage. The urethra also becomes greatly elongated and tortuous; and is diverted from the natural direction—this varying with the form of enlargement. When the median portion is enlarged, there is a more or less angular curvature of the canal at the prostatic point. When, in addition, there is enlargement of one lateral lobe, the urethra is curved also laterally in the direction of the enlarged lobe. The lateral deviation may occur also when there is enlargement of the middle lobe; but it then affects both sides.

Fig. 903.—Bladder laid open, showing Enlargement of Urethral Portion of Prostate.

The inner orifice of the urethra also undergoes changes. Enlargement of the posterior part of the middle portion of the prostate gives it a crescentic form, with the convexity directed upwards; and, in enlargement of either lateral lobe, the convexity of the crescent lies towards the side opposite the enlarged lobe. Sometimes, when there are two or more irregularly enlarged lobes, the orifice is very much distorted, elongated, and tortuous. In cases of valvular or pedunculated projections from the posterior portions, the orifice may appear to be overlapped altogether. This condition existed in the case from which the accompanying drawing (Fig. 903) was taken; the third, or median lobe forming a pedunculated tumour which acted like a valve and obstructed the exit of the urine from the bladder, though it did not offer any obstacle to the introduction of a catheter.

The elongation and expansion of the prostatic portion of the urethra give rise to an increase in its capacity, so that it sometimes holds two or three ounces of urine; and the elongation will carry the neck of the bladder upwards and behind the pubes, to a considerable distance from its normal position.

While the lateral enlargements cause the urethra to assume a somewhat tortuous course, the middle lobe, if hypertrophied, may readily occasion retention,

by projecting against the entrance to this winding channel, and falling over it like a valve whenever the patient attempts to pass urine, as in Fig. 904. In this condition no urine is passed until by accumulation within the bladder the neck has become so stretched that the valve-like obstruction no longer closes the orifice. Then a small quantity of urine is expelled; the neck of the bladder collapses, and before the cavity is completely emptied, the orifice is blocked by the projecting middle lobe, and the flow ceases. Thus a certain amount of urine is always retained, which is commonly termed the "residual urine,"

and none escapes till the bladder is in a state of considerable tension. As the middle lobe increases in size, a greater degree of stretching is necessary before urine can escape. Under this constant tension the bladder slowly yields and becomes dilated, its walls are thickened by fibroid tissue, and it gradually becomes completely "atonic," losing all active power of contraction. At last a condition is reached in which urine flows only when the bladder is greatly distended, and the escape of a few drops is sufficient to render the obstruction complete, and thus a condition of almost constant dribbling is established. This forms the most typical variety of prostatic obstruction. Less commonly, the obstacle to the passage of urine is of such a nature that it can be forced by increased pressure, and we then find the muscular coat of the bladder hypertrophied, as in stricture of the urethra. In still more rare cases the middle lobe lies between the enlarged lateral lobes, thus propping the neck of the bladder open, and then true incontinence may occur with constant dribbling of urine.

Fig. 904. — Results of enlarged Prostate: Bladder enlarged; Ureters dilated; Chronic Disease of Kidneys.

The effect on the kidney will vary according to circumstances. If the bladder is in a constant state of over-distension, a similar increased tension will occur in the ureters, as it is evident that increased force will be required to drive the urine through their orifices. We consequently find all the signs of increased tension already described (p. 994); dilated ureters and pelvis, absorption of the pyramids, chronic interstitial nephritis, &c. (Fig. 904). Finally, should decomposition occur in the urine retained in the bladder, it may extend through the orifice of the ureter to the kidney; and in this way a large proportion of patients suffering from prostatic disease die of septic suppurative nephritis.

Moral Effects of Enlarged Prostate.—The irritation of a congested and enlarged prostate will excite libidinous ideas in the aged, which may lead to the perpetration of acts of indecency—such as exposure of the person, indecent assaults on children, or to a general deterioration of the moral tone.

But not only does the diseased state of this body thus excite a depraved condition of the mind; the converse also will happen. And if the true history of many cases of prostatic congestion and hæmorrhage were told, the diseases would be found to have begun in irregular sexual or erotic excitement by which the genital organs have been over-stimulated.

Bar at the Neck of the Bladder.—Under this name has been described a transverse ridge obstructing the internal orifice of the urethra, and causing symptoms exactly analogous to those produced by hypertrophy of the middle portion of the prostate. According to Thompson, the fold is in the great majority of cases actually caused by an outgrowth from the middle portion of the gland. In exceptional cases, however, it may be due to hypertrophy of the muscular fibres at the neck of the bladder, produced by long continued irritation, usually caused by chronic cystitis from stone or stricture. Lastly, in very rare cases, a valve-like fold of mucous membrane may be drawn up by enlargement of the lateral lobes without affection of the median portion of the gland.

The **Symptoms of Enlarged Prostate** arise primarily from the mechanical obstacle offered to the escape of the urine. The first symptoms usually consist in the feeling of a necessity to strain slightly before the urine will flow; and then, after the bladder has apparently been emptied, in the involuntary escape of a small quantity of urine. The patient also finds that he is much longer than usual in emptying the bladder; for though the stream flows freely enough as soon as it has once begun to escape, yet it cannot be properly projected, the bladder having, to a certain extent, lost its tonicity. It commonly happens that the more the patient strains the less readily will the urine come away, whereas when he remains quiet, it will usually flow with more freedom. This is especially the case in pedunculated enlargements of the middle lobe. About this time frequency of micturition usually becomes a marked feature, especially at night. In fact, the great majority of patients apply to the Surgeon, not on account of difficulty in passing water, but because they are called upon to perform the act of micturition too frequently. This condition may gradually increase till it amounts to actual dribbling. The frequent discharge of a small quantity of urine may lead the incautious Surgeon to suppose that the patient is affected with true incontinence of urine or with irritability of the bladder. This error may always be guarded against by careful examination of the pubic region by percussion and palpation. Dulness will often be found extending half-way to the umbilicus, and the tense distended bladder may be readily felt above the pubes. If there is any doubt the patient must be made to pass water, and immediately afterwards a soft catheter must be passed. In this way the presence of residual urine and its quantity are determined.

The symptoms may for a long time remain limited to frequency of micturition with some difficulty in the act. The urine remains acid and normal in every respect, and the patient suffers but little, if at all, in his general health. The condition is, however, always one of considerable danger. The over-distended bladder is always prone to slight attacks of cystitis from exposure to cold or other causes. The urine then becomes cloudy from excess of mucus, and often acquires an offensive fishy smell, while still remaining acid. The mucus accumulates in the pouch behind the enlarged prostate, and ammoniacal decomposition readily takes place. This may occur without the passage of

instruments, but in a considerable proportion of cases it is not noticed before the use of the catheter has been commenced. Should it happen, the cystitis becomes more acute, and the symptoms of septic poisoning—febrile disturbance, great depression, brown tongue, nausea, delirium, &c.—may set in and terminate fatally, when septic inflammation of the kidneys, by extension up the ureter, will usually be found to have been the immediate cause of death.

Complete Retention of Urine from Enlarged Prostate is a common complication of the disease. It may arise in a patient who has not been able to empty his bladder for some time, and is little more than an aggravation of his usual condition, or it may occur in an old man whose prostate is considerably enlarged, but who, under ordinary circumstances, gets rid of his urine without difficulty. In the latter case it is due to congestion and swelling of the diseased gland, usually induced by exposure to cold, or by alcoholic or venereal excesses. It is especially apt to occur after drinking the sour bad wines usually provided at public dinners.

Diagnosis.—The exact condition of the enlarged prostate can be ascertained only by examination through the rectum and urethra. By rectal exploration with the finger, the degree of enlargement of the lateral lobes can best be ascertained: though, as in many cases the end of the finger cannot reach the further extremity of the gland, it will be impossible to say to what extent the hypertrophy has extended. The urethral exploration must be conducted by means of a long gum-elastic or a silver prostatic catheter, and will afford information that rectal exploration cannot give; by it are ascertained approximately the size of the middle lobe, and the condition of the urethra as to elongation and curve.

The diagnosis of enlarged prostate has to be made from, 1, Stricture of the Urethra; 2, Calculus of the Bladder; 3, Vesical Tumour; 4, Chronic Cystitis; 5, Atony of the Bladder; 6, Paralysis of the Bladder.

1. In *Stricture* the stream of urine is small, but the jet is increased by straining, while in enlarged prostate the stream is dribbling, but not reduced in volume, and straining only makes matters worse. Stricture most commonly occurs before middle life, prostatic disease always after. In stricture the obstruction is within six inches of the meatus: in prostatic disease it is at least seven from the orifice. It is not wise, however, to trust too implicitly to measurements in inches, as the penis varies considerably in length. If the finger be passed into the rectum, it can at once be determined whether the point of obstruction is in front of the apex of the prostate.

2. *Calculus* presents many symptoms in common with enlarged prostate, and its more special symptoms may be absent. In stone the frequency of micturition is greater by day, in prostatic disease it is worse at night. The presence of a small quantity of florid blood in the urine passed after exercise should make the Surgeon strongly suspect the presence of a stone; but the use of the sound will alone lead to an exact diagnosis.

3. *Vesical Tumour* gives rise to more pain and tenderness on the introduction of instruments than prostatic enlargement; and the urine generally contains blood and mucus, often with sabulous matter. Microscopic examination of the contents of the urine may show the presence of the tissues of the tumour. Malignant tumours may often be felt through the rectum; while villous growths give rise to the almost constant presence of blood in the urine.

4. In *Chronic Cystitis*, without complication, the absence of the physical signs of enlarged prostate, as ascertained by examination by the rectum and urethra, will establish the diagnosis.

5. *Atony of the Bladder* is, as before stated, very commonly associated with enlarged prostate. Its absence would be shown by the urine flowing from the catheter in a steady stream, not influenced by the respiratory movements, indicating an active contraction of the bladder.

6. True *Paralysis* of the bladder, accompanied by a similar affection of other parts, is recognized by its concomitant conditions, and by the absence of physical signs of enlarged prostate, and, as in atony, by the passive nature of the flow of urine through the catheter.

Treatment.—In the treatment of enlarged prostate, little can be done by medical means ; though the patient's condition may be somewhat ameliorated by remedies calculated to lessen irritation about the urinary organs, and to improve the condition of the urine. If it be very acid, alkalies with hyoscyamus should be given. If the symptoms of chronic cystitis make their appearance, the various remedies recommended in the treatment of that disease may be given. If hæmorrhage occurs, tincture of perchloride of iron, infusion of uva ursi, or gallic acid, will be useful. Counter-irritation, the application

Fig. 905.—Elbowed Catheter.

of iodine, and other measures intended to promote absorption of the enlarged gland, are not of the slightest service.

In the great majority of cases the sole treatment of enlarged prostate consists in the regular use of the catheter, in order to draw off retained urine ; and when once this treatment has been commenced, it must be continued for the remainder of life, the patient being taught to use the instrument for himself. In almost all cases a Jaques's flexible india-rubber catheter can be passed into the bladder. Its use is so perfectly painless and free from danger, that it should always be tried before adopting more severe measures. If from any cause it be necessary to retain such an instrument, Hutchinson uses a nozzle with rings passed into the orifice of the india-rubber catheter, and fitted with a "styletted plug." The nozzle is about three-quarters of an inch in length, and is fitted accurately by the plug. The stylet reaches about two inches down the catheter so as to stiffen it. With such an instrument in use, the patient need not be confined to bed. If the soft rubber catheter will not pass, by far the most convenient instrument in the majority of cases is the soft French "elbowed" catheter—the *cathéter à coude*, of the size and shape here represented (Fig. 905). The stem is soft and pliable, but the angle and eyed point are made of firm gum-catheter material. By keeping the point well up against the urethra, it will often slip in very easily and smoothly in cases of enlarged prostate. These catheters are made with their points bent at different angles or with double elbows, instead of single, and very often when one will not pass, another of a slightly different form will slip in readily.

The size of the instrument is of some importance. As a rule, No. 8 or 9 passes most easily. Nothing is gained by using a smaller instrument, as the passage through the diseased prostate, although it obstructs the flow of urine, is always larger than that through a healthy gland.

If neither of these instruments will enter the bladder, a common French conical instrument may pass; but this very rarely succeeds when the cood catheter fails.

A common gum-elastic catheter of full size, which may be bent to any angle in hot water and fixed by immersing it in cold, may pass when other instruments fail. Sometimes, if it be bent to a curve like that of a lithotrite, it may slip over the enlarged middle lobe. It must be remembered that the heat of the urethra soon causes the catheter to lose the form impressed upon it, and consequently, if it does not enter at once, prolonged attempts to pass it are useless.

Brodie recommended that a gum-elastic instrument, long and of large size,

Fig. 906.—Enlarged Middle Lobe of Prostate, arresting progress of the Catheter

on a well-curved stylet so that it might preserve its curve when that is withdrawn, should be kept in readiness for these cases. A manoeuvre mentioned by Brodie will often be of use in surmounting a large middle lobe: viz., after passing the gum-elastic catheter as far as it will go, to withdraw the stylet slightly, so as to tilt up the point of the catheter, which then slips over the obstacle.

If none of the foregoing means succeed, the Surgeon must have recourse to silver instruments. If the prostate be much enlarged it may be necessary, in order to reach and empty the bladder, to use a prostatic catheter. This instrument should be of large size, about No. 12. In order properly to enter the bladder, which is carried away from the surface by the elongated urethra, the prostatic catheter should be about four inches longer than an ordinary one; and, as the neck of the viscus is usually pushed up high behind the pubes by the projection upwards of the lateral lobes, the curve of the

instrument should be greater and longer than usual. I find the best-shaped prostatic catheter to be one the curve of which is exactly the third of the circumference of a circle five-and-a-half inches in diameter. The eyes should be large and rounded; and I have found it of use to have the lower end of the stylet provided with a piston-plate, so that, by withdrawing this the mucus may be sucked in through the eye of the instrument. In introducing the catheter, care must be taken when the point enters the prostatic urethra to depress the handle well between the thighs, while the instrument is drawn slightly towards the pubes, lest the end hitch against the enlarged middle lobe (Fig 906). If it be simply depressed, without at the same time being held back a little, it will probably tunnel the obstruction. In some cases the ordinary catheter passed in the same way will enter more easily than the prostatic. It is sometimes possible to lift the catheter over the obstruction by pressing on it with the finger in the rectum. In fact, no one curve or one kind of instrument will answer in all cases. If it is necessary to use a rigid instrument, I certainly think a silver instrument is safer and more easily managed than the gum-elastic. It might be supposed that less chance of mischief would result from the gum-elastic than from the metallic catheter, as being the softer and more yielding instrument; but this is erroneous, if the stylet be allowed to remain in, as it is then as rigid at the point, as hard, and as likely to penetrate soft structures as a silver one would be.

The commencement of catheterization in cases of enlarged prostate cannot be regarded as altogether free from risk. The patient is liable to an attack of fever such as may follow the introduction of an instrument for other purposes, and the precautions mentioned at p. 1125 must be carefully observed. Exposure to cold is especially to be avoided after the catheter has been used. Before the instrument is passed, the patient should empty his bladder as completely as possible, in order that the amount of the residual urine may be ascertained. If this be about three or four ounces the bladder should be emptied every morning and evening, whilst if this amount be much exceeded the catheter must be passed three or four times in the twenty-four hours.

The patient should use a soft catheter if possible, and the Surgeon must give careful directions concerning the cleansing of the instrument.

In cases complicated with severe cystitis and great irritability of the bladder which have resisted simpler treatment, drainage of the bladder may be the only means of saving the patient from fatal exhaustion or septic poisoning. This may most readily be done by introducing a tube through an incision into the membranous urethra (p. 1119); or suprapubic cystotomy may be performed, as first practised by Thompson in 1869, the opening being maintained by a gum-elastic catheter fitted with a silver shield, and provided with a rubber bottle to receive the urine. The suprapubic method has the advantage of allowing a thorough investigation of the bladder and prostate, but it is only available if the patient's condition is favourable.

Operative Treatment of Enlarged Prostate.—Various operative procedures have been proposed from time to time for the relief of difficult micturition from enlarged prostate or bar at the neck of the bladder. One of the first of these was Mercier's operation of division of the bar at the neck of the bladder by means of an instrument shaped like a lithotrite, the male blade of which was represented by a concealed knife. Mercier also devised another

Operative Treatment of Enlarged Prostate.—Various operative procedures have been proposed from time to time for the relief of difficult micturition from enlarged prostate or bar at the neck of the bladder. One of the first of these was Mercier's operation of division of the bar at the neck of the bladder by means of an instrument shaped like a lithotrite, the male blade of which was represented by a concealed knife. Mercier also devised another

instrument like a lithotrite by which he could cut a deep groove through the bar. Bottini of Genoa has revived Mercier's operation, but uses a galvanocautery instead of a knife. Such operations have not, however, been attended with sufficient success to inspire Surgeons in general with any confidence in their utility.

Of the various methods which have been devised for attacking the enlarged prostate from the perinæum, the simplest is that practised by Reginald Harrison. The operation consists in dividing the prostate through the ordinary incision employed in digital exploration of the bladder (p. 1119). The projecting bar is divided partly with a probe-pointed bistoury, and partly by divulsion with the finger. A large gum-elastic tube is then inserted, and through it a soft catheter is passed into the bladder for drainage. The presence of the tube maintains the channel made by division of the prostate. It must be retained for many weeks, until urine can be passed voluntarily by the urethra, or a catheter readily introduced.

By far the most radical operation, however, for enlarged prostate consists in opening the bladder above the pubes and removing the obstructing portion of the gland—**suprapubic prostatectomy**. This operation, which had been performed by Belfield of Chicago, and by Trendelenburg, Socin and others on the Continent was first advocated in this country by McGill of Leeds in 1888, who published three cases in which he had successfully performed it with great benefit to the patient.

The operation is performed in the same way as in suprapubic lithotomy until the bladder is opened (p. 1044). The mucous membrane over the projecting part of the prostate is snipped through with scissors, and the enucleation effected with the finger and forceps. Hæmorrhage is arrested by irrigation with hot water. A drainage tube is inserted into the bladder and retained for two or three days.

This operation has now been performed in a large number of cases with considerable success, and in several instances calculi in the post-prostatic pouch have at the same time been removed. The suprapubic method is generally regarded as preferable to the perinæal in most cases as it allows a more thorough removal of the obstruction. The operation is not however unaccompanied by danger, and if the patient can easily pass a catheter for himself, and is free from any other complication, it seems hardly justifiable to submit him to an operation which may prove fatal. If, however, the patient cannot pass the catheter, or suffers from constant cystitis with great irritability of the bladder, or from frequent hæmorrhage, some operative procedure gives the best chance of relief. Suprapubic drainage has for some time been recognised as the best treatment in cases of prostatic disease which cannot be relieved by catheter, and experience seems to show that it is not only justifiable, but advisable to extend the operation to the removal of the cause of obstruction if possible.

Castration for Enlarged Prostate.—The considerations which have recently led to the performance of castration in certain cases of enlargement of the prostate are chiefly, the effect of removal of the ovaries in causing diminution in size of fibroid tumours of the uterus, and the well known fact that removal of the testes in young animals prevents the development of the prostate, and in adult animals causes its atrophy.

In a certain number of cases it has also been observed in man that removal

of the testicles was followed by atrophy of the normal prostate. The suggestion to perform castration with the definite object of causing shrinkage of the hypertrophied gland was prominently brought forward by White of Philadelphia, in 1893, but the operation was first performed by Ramm of Christiania in the same year. The patient, seventy-three years of age, had suffered from symptoms of enlarged prostate for fifteen years, and came under treatment for complete retention. The prostate rapidly diminished in size after castration and the patient recovered good power of micturition.

In this country the operation was first performed by Mansell Moullin, and he has been followed by Fenwick, Heath, and others. In the cases which have so far been recorded, more than twenty in number, the result has been almost uniformly satisfactory. In several instances the diminution in the size of the gland has been appreciable within a few days after the operation, and has gradually continued until, after several weeks, complete atrophy has taken place. Further experience alone can show whether castration is capable of producing this result in all varieties and stages of chronic enlargement, and what amount of impairment of the muscular power of the bladder is capable of recovery.

Sufficient evidence is before us to justify a continued trial of the treatment in cases of enlarged prostate in which the severity of symptoms calls for radical measures. Few men of the age at which the operation is likely to be required will refuse to submit to it if further experience can show results equal to those hitherto obtained.

Treatment of Complete Retention from Prostatic Enlargement.—

In these cases the patient must be relieved by an instrument as soon as possible, as elderly people are liable to suffer severely if there is any delay, fever soon setting in, which may be fatal.

It cannot be too strongly insisted on that in these cases there is no actual narrowing of the canal. The enlarged prostate is no doubt swollen, but there is always sufficient space left for the passage of the largest catheter, if only the proper way can be found. Nothing is gained by using small instruments; anything below No. 8 or 9 (English) is likely to wound the swollen mucous membrane, and cause troublesome hæmorrhage. In complete retention the various modes of overcoming the obstacles in the prostate, which have already been described, must first be attempted, beginning with soft instruments, and using silver ones only after these have failed. If the retention is thus relieved, it becomes a question whether the catheter should be left in the bladder or withdrawn after the viscus is emptied. As a general rule, it is certainly far better not to leave the catheter in, for the reasons given at page 1125. The instrument should be introduced twice in the twenty-four hours; and care should be taken, if possible, to empty the pouch behind the prostate by depressing its point. Should the mucus be very viscid and offensive, the bladder may be washed out. After the bladder has been emptied for the first time, it will be found to refill in the course of a very few hours, usually in six or eight, the secretion of the kidneys appearing to be set free on the removal of the pressure.

Should any great difficulty be experienced in introducing the catheter, it may be thought desirable to leave it in the bladder for two or three days; and then a gum-elastic one is always to be preferred, as in these circumstances it presents a great advantage over the silver catheter, becoming soft, accommo-

dating itself to the shape of the parts, and not being so liable to irritate the mucous membrane with its point, which, dipping down into the pouch behind the prostate, acts as a siphon, and empties this part of the bladder far better than a silver catheter could do.

When the bladder has been relieved, the patient must be freely purged. Belladonna suppositories are often of use, but if there be much pain, opium or morphia will be preferable. In a few days the congestion of the prostate passes off, and the patient may again be able to pass water unaided. In many cases, however, the bladder of an old man which has, perhaps, not been completely emptied for some time, becomes permanently atonic after a single attack of retention, and he is never able again to dispense with the catheter.

It becomes an important question what course should be pursued in those rare cases in which the Surgeon *fails to pass any instrument into the bladder*. Aspiration of the bladder above the pubes may perhaps be tried as a first resource, and after some hours, during which the patient has been kept in bed, another attempt made to pass a soft catheter. The hope of such a successful result is small, and aspiration in prostatic retention cannot be regarded with much favour. In these cases three lines of practice may be adopted: *tapping the bladder above the pubes, tapping from the perinæum, and suprapubic cystotomy*. Puncture of the bladder through the rectum is not a safe procedure, whilst "tunnelling the prostate," that is to say, pushing a silver catheter forcibly through the obstruction into the bladder, may be regarded as a method of treatment belonging to a past age of Urinary Surgery, ruder than the present.

Tapping the Bladder above the Pubes consists in making a small incision about half an inch in length through the integuments, exactly in the mesial line, immediately above the pubes, and then pushing a specially constructed curved trochar, with its concavity downwards and backwards, into the bladder behind that bone, and consequently below the reflection of the peritoneum. After the bladder has been emptied, the cannula or a gum-elastic tube must be left in for the escape of the urine, whilst the continuity of the natural passage is being restored. When the bladder is greatly distended, in consequence of retention from enlargement of the prostate or any other cause, the peritoneal reflection is carried up with it, and a considerable portion of the anterior wall of the organ uncovered by peritoneum is left above the pubes. In a case of unrelieved retention from stricture, in which the patient died suddenly during the administration of chloroform, and which I had an opportunity of dissecting, I found that the summit of the bladder reached to five inches above the symphysis pubis, and was only two inches below the umbilicus; that the line of reflection of the peritoneum was $3\frac{1}{2}$ inches above the bone; and that the space uncovered by serous membrane was $2\frac{1}{4}$ inches wide. The bladder contained nearly forty ounces of urine, the retention having lasted forty-eight hours.

Tapping the Bladder from the Perinæum has especially been advocated by Reginald Harrison. The patient being fixed in the lithotomy position, the Surgeon passes his left index finger into the rectum to serve as a guide. A straight trochar and cannula is introduced in the middle line of the perinæum three-quarters of an inch in front of the anus, and is pushed straight into the bladder through the middle of the prostate. The trochar is withdrawn and the cannula fixed with tapes. Harrison allows the patient to leave his bed at the end of a week or ten days, a tube passing to an india-rubber

urinal or closed with a clip being attached to the cannula. The drainage is continued until urine again finds its way along the urethra. It is doubtful whether this method of tapping is as free from risk as that performed above the pubes.

Suprapubic Cystotomy has been performed in some cases of prostatic retention as a substitute for simple tapping. If the patient's condition is favourable it is probable that this is the best course to pursue in these rare cases. Whatever method of drainage be adopted it is frequently necessary to continue it permanently, and the suprapubic opening allows the prostate to be felt, and possibly the obstructing portion dealt with at a subsequent occasion. A small opening only is necessary in the bladder, and its edges may in some cases be drawn up to the skin wound with sutures.

Hæmorrhage occasionally causes trouble in cases of enlarged prostate, and in those rare instances in which there is retention and distension of the bladder with blood clot, suprapubic cystotomy is especially indicated.

Atrophy of the Prostate sometimes occurs. It may be the result of exhausting disease, especially phthisis, of old age, of mechanical pressure from tumours or calculi, or of local disease of the gland itself. Congenital deficiency of the prostate may also occur.

PROSTATIC CALCULUS.

Prostatic Calculus differs from all other urinary concretions in situation and composition, being formed in the ducts of the prostate gland, and composed principally of phosphate of lime and some animal matter ; usually about 85 per cent. of the phosphate, to 15 of the organic ingredients. The concretion is said to consist sometimes of carbonate of lime (p. 1030). It generally occurs in old people, though it may sometimes be met with in young subjects. From a lad of nineteen, whom I cut for vesical calculus, I extracted two prostatic concretions.

Characters.—Prostatic calculus is usually of a grey or ashy colour somewhat triangular in outline, smooth and polished (Fig. 907), having facets, being very hard, and seldom much larger than a cherry or plumstone ; though it may occasionally attain a considerable bulk, having been met with as large as a hen's egg, and then presenting a branched or irregular appearance. Though usually but one or two exist, which are sometimes deposited in a kind of cyst in the gland, as many as thirty or forty have been met with, the ducts being filled, and its whole tissue being studded with them.

Fig. 907.—Prostatic Calculus.

Symptoms.—Calculus in the prostate gives rise to a sense of weight, pain, and irritation in the perinæum, sometimes to retention of urine, and, in fact, to the ordinary symptoms of enlarged and irritated prostate ; it often occasions a tolerably free discharge of mucus in the urine. On introducing a sound, this passes over the stone, sometimes rubbing or striking it with a distinct grate or click before its beak enters the bladder. This is increased by the finger in the rectum pushing the organ up, and thus bringing the stone into more direct contact with the sound. In some instances the calculus is deeply imbedded in the prostate, and cannot be touched by the sound. In these cases the stone may usually be felt through the rectum. If there be many

small calculi in a sacculus in the prostate, they may be felt by introducing the finger into the rectum, when a peculiar crackling or grating sensation may be experienced by the rubbing together of the calculi, something like that produced by beads in a bag.

The **Treatment** of prostatic calculi will depend upon the situation, size, and number of the concretions. When they are large, single, or at most two or three in number, readily struck with the sound, and situated on the urethral surface of the organ, the ordinary median operation may advantageously be performed, and the calculus removed with a scoop or forceps. If the calculi be small and very numerous, not to be felt with the sound, but passing through the rectum, it will be wiser not to have recourse to a perineal operation, as it could not remove the whole of the concretions. In such circumstances, a palliative treatment directed to the subduing of the irritation of the prostate and the use of the catheter to relieve retention, is the only course to pursue. When prostatic and vesical calculi occur together, the same operation will be the patient of both forms of the disease.

TUBERCLE OF THE PROSTATE.

Tubercle of the Prostate is not uncommonly met with. It usually forms a part of extensive tuberculous disease of the genito-urinary tract. In fact it is rare to find it sufficiently advanced for a diagnosis to be made without one or both epididymides being similarly affected, and it is often very difficult to tell where the disease originally commenced. The vesicular seminales are usually implicated, and the tuberculous infiltration frequently extends to the floor of the bladder. Not uncommonly it is associated with tubercle of the kidney. The *post-mortem* appearances are those of tubercle elsewhere. Softening yellow masses are found usually near the urethral surface. After a time the mucous membrane gives way, and a ragged cavity with yellow walls is left in the floor of the prostatic urethra. Sometimes the tuberculous abscess may open into the rectum, and thus a fistula may be left between the urethra and the bowel. More rarely it causes an abscess pointing forwards in the perinæum. Tubercle in the lungs is usually present at death. The *Symptoms* vary much, according to the situation of the ulceration. If it is limited to the prostate, it may cause surprisingly little disturbance. In a case which occurred in University College Hospital, the patient died of tuberculous meningitis, some months after castration for tuberculous testis. At the *post-mortem* examination two cavities were found in the prostate large enough to admit the top of the thumb, but the patient had made no complaint of any urinary trouble. Berkeley Hill pointed out that the disease not uncommonly follows gonorrhœa, and that the only symptoms in the early stages are a chronic gleet and perhaps weight in the perinæum. When the disease extends to the bladder there may be extreme symptoms of irritable bladder. Digital examination by the rectum shows the prostate to be hard, nodular, and irregularly enlarged. Sometimes a softening part may be detected in it. The vesiculæ seminales, if they can be reached, are usually found to be enlarged. There may be a purulent discharge from the urethra, and pus in the urine. The detection of the tubercle bacillus would determine the nature of the case. The *Treatment* in the early stages when the diagnosis is doubtful should consist in attention to the general health and

any existing urethral discharge. If symptoms of cystitis supervene injections of iodoform should be used and in some instances cystotomy may be necessary. A tuberculous abscess in the prostate may require to be opened in the perinæum, scraped and drained.

CARCINOMA OF THE PROSTATE.

Carcinoma does not commonly attack the prostate, but I have met with several instances of the disease. The form met with is usually the hard glandular carcinoma; one case of colloid has been recorded by Stanley Boyd.

I have seen the disease in a man about seventy years old; he died with secondary growths in the lymphatic glands and liver.

The **Symptoms** in the early stages are obscure pain and irritability about the neck of the bladder, with the occasional passage of blood. As the disease may occur in patients who are already suffering from the effects of simple enlargement of the prostate, the early symptoms may closely resemble those occasioned by a stone in the post-prostatic pouch or an attack of subacute prostatitis. Digital examination by the rectum will probably detect a hard, ill-defined mass, occupying the situation of the prostate, nodular on the surface, and often peculiarly fixed. It is slightly tender on pressure. The rapid increase in size, with obstruction to the passage of urine, and frequent hæmaturia and increasing pain, will reveal the true nature of the disease.

The vague character of the symptoms of carcinoma of the prostate as compared with those of a primary growth in the bladder may be explained by the different nature of the two tumours. Carcinoma of the bladder is of the squamous variety and, as a rule, rapidly ulcerates, whereas the deeply-seated glandular carcinoma of the prostate may reach a considerable size before ulceration occurs.

The **Treatment** is palliative. Morphia suppositories may relieve the pain, and if the symptoms be extreme, drainage of the bladder may be required. Although excision of the prostate for carcinoma has been performed by Billroth and others, the operation can hardly be regarded as a procedure of recognized usefulness.

CHAPTER LXXI.

DISEASES OF THE URETHRA.

URETHRITIS.

Simple Inflammation of the Urethra is especially apt to occur in strumous, rheumatic, or gouty individuals, from slight sources of irritation that would not excite it in more healthy constitutions. In strumous children it may arise from worms in the intestines, or from gastric irritation; and in gouty or rheumatic subjects, it appears often to occur in connexion with an acid state of the urine. Excessive beer drinking may cause a slight discharge from the urethra—the “Biertripper” of the German students. In other cases, the irritation of a stricture, the passage of instruments, or ordinary sexual intercourse, may occasion the disease, without there being anything of a specific character about it. Contact with women who are out of health, pregnant, or suffering from leucorrhœa, often gives rise to local irritation of this kind. Urethritis, especially when arising from sexual intercourse, is frequently mistaken for gonorrhœa. From this it may, as a rule, be distinguished by the less intense degree of inflammation, and by the absence of the secondary consequences that frequently follow true gonorrhœa; yet, in many instances, the diagnosis is extremely difficult, especially from the subacute forms of gonorrhœa that are common in London. Increasing experience seems to show that the decision as to the gonorrhœal or simple character of urethritis is best determined by the presence or absence of the gonococcus in the discharges.

Symptoms.—Urethritis is characterized by heat, pricking, and tension about the urethra for a day or two, followed by muco-purulent discharge, often rather profuse, and accompanied by some ardor urinæ. The symptoms are not severe, and the disease usually subsides at the end of a week or ten days; but sometimes it becomes chronic, especially if conjoined with stricture and is then extremely troublesome, particularly in gouty individuals.

In the **Treatment** of urethritis the bowels should be kept open, and salines freely administered; in cases in which there is reason to believe that the affection is of gouty origin, small doses of colchicum, in combination with alkalies, will be found of especial service. The use of emollient or slightly astringent injections, such as opiate lotions, or a very weak solution of acetate of lead, with belladonna, will be found serviceable as the disease is on the decline, but not until then; and when the affection has reached a chronic stage, small doses of copaiba may advantageously be administered. The diet in all cases should be of the blandest character, stimulants of all kinds being interdicted.

If the disease be conjoined with slight stricture, it may not unfrequently give rise to temporary retention of urine. This may, however, most commonly

be readily relieved by leeches to the perinæum, the warm hip-bath, and salines, with, perhaps, opiate suppositories, and plenty of demulcent drinks. The catheter should not be used, if it be possible to give relief without it.

GONORRHOEA.

Gonorrhœa is a specific disease, accompanied by inflammation and an abundant muco-purulent discharge; affecting the urethra most commonly, but also the other mucous membranes of the genital organs, as of the prepuce and the glans in the male, and of the vulva and vagina in the female.

The urethra is the usual seat of gonorrhœa in the male; and the disease may be looked on as an infective urethritis. Its seat of greatest intensity is usually the fossa navicularis; but it may extend over a much greater surface, affecting the entire length of the canal, and even the whole mucous lining of the bladder. In the female it commonly spreads over the extensive mucous surface of the external organs of generation, and sometimes invades the uterus and Fallopian tubes.

Cause.—Gonorrhœa has its origin in the female, and is possibly developed in prostitutes without infection from the male. It is a highly infective inflammation of the mucous membrane of the vagina, predisposed to by the decomposition of retained semen and of foul discharges, the result of repeated acts of indiscriminate intercourse without proper attention to cleanliness. It is impossible to say clinically where urethritis or vaginitis ends, and infective gonorrhœa begins. In the male, gonorrhœa arises in all cases from communication of the specific poison from the female by sexual intercourse.

The poison of gonorrhœa differs entirely from those of the venereal diseases described in Chapter XXXVI., as has been fully proved by inoculation; these diseases not being capable of reproducing one another in any circumstances. The pus of gonorrhœal urethritis always contains a specific organism—the *gonococcus* of Neisser, which is undoubtedly the cause of the disease. It can readily be demonstrated by drying a thin layer of the pus on a cover-glass and staining it for a few minutes in an alcoholic solution of methyl-violet. The gonococcus occurs in pairs or groups, and is met with in the interior of the epithelium and pus cells. The organism has been cultivated outside the body in fluid media and on blood-serum and gelatine; and inoculations of pure cultivations into the normal urethra have reproduced the disease. Bokai inoculated six students with the organism, which had been cultivated in suitable fluids, and in three gonorrhœa followed. Bockhart successfully inoculated the organism in the urethra of a man after it had been cultivated to four generations on prepared gelatine; and Bumm produced typical gonorrhœa by the introduction into the healthy female urethra of the organism cultivated to the twentieth generation on blood-serum.

It is important to remember that the gonococcus is not distinguishable by its form alone from other varieties of diplococcus, such as one which Lustgarten and Mannaberg found constantly in the normal urethra. Roux has, however, shown that the gonococcus can be distinguished by the fact that it does not stain by Gram's method, whereas the others do. Lustgarten and Mannaberg also found in the normal urethra an organism like the smegma bacillus, which showed the same staining reactions as the bacillus tuberculosis, and the staphylococcus pyogenes aureus. Recent observations tend to show that the

chief complications of gonorrhœa, such as suppurating bubo, are due to the associated organisms of suppuration and not to the gonococcus itself.

The suppurative inflammation of gonorrhœa has these peculiarities: 1. It has a distinct and lengthened period of incubation; 2. It rapidly propagates itself along the mucous tracts that it affects; 3. It is contagious in the highest degree not only when the pus is applied to, and, as it were, rubbed on the mucous surfaces of the generative organs during coitus, but when it touches other mucous surfaces; and, 4. It is sometimes attended with constitutional phenomena partaking of a pyæmic character.

Character.—Gonorrhœa is usually looked upon as a purely local affection of the genital organs; but although in the early stages it is doubtless a local affection, yet it is occasionally followed by a train of very characteristic phenomena, that can scarcely be looked upon in any other light than as the result of constitutional infection; the more so, as some individuals never have gonorrhœa without the disease being followed by these sequences, whilst others are altogether exempt from them. The parts that are secondarily affected are chiefly the fibrous tissues, and the mucous and cutaneous surfaces. The affections of the *fibrous tissues* give rise to so-called rheumatism and to various forms of inflammation of the testicle and of the sclerotic. The affection of the *mucous membranes* displays itself in specific inflammation of the urethra. The occurrence of these various affections, assuming as they do a specific character so distinctly marked that they can at once be characterized as gonorrhœal, certainly tends to show that the disease impresses the constitution in a peculiar manner, somewhat analogous to syphilis or pyæmia; though in a minor degree, and with much less certainty, than these diseases.

The **Symptoms** of gonorrhœa in the male may be divided into three stages:—1. The Incubative Stage, or the period of Irritation; 2. The Acute Inflammatory Stage; and 3. The Chronic Stage.

1. **Incubative Stage.**—The first stage, that of irritation, usually commences from two to three days after connexion, when the patient begins to experience some degree of heat, itching, and general irritation about the penis. The parts of the urethra are somewhat red and swollen; its orifice gapes; and on squeezing it, some mucus exudes. This stage usually continues for three or four days from the time of infection, but sometimes for six or eight, when it terminates in the second, which is one of active inflammation.

2. **Acute or Inflammatory Stage.**—The discharge now becomes abundant, thick, and of a greenish-yellow colour; there is great pain in micturition, with considerable heat and smarting, and the urine, which flows in a diminished stream, is passed with increased frequency. The urethra is swollen, firm, and cord-like to the touch; the whole penis, indeed, looks red and tumefied. As the disease advances, and the bulbous portion of the urethra becomes affected, weight and tension in the perinæum will be complained of. If the prostatic portion be the seat of disease, there will be heat and weight about the anus, with frequency of micturition and some strangury. During the whole of this period there is generally a good deal of constitutional disturbance, restlessness, and fever.

One of the most troublesome symptoms in this stage is the occurrence of **Chordee**, which consists in painful erections at night, with a twist in the body of the penis, which is usually curved downwards.

3. **Chronic Stage.**—The acute symptoms usually continue for about a fortnight.

ght, when the third stage, that of subacute or chronic inflammation, sets in. During this period of the affection the inflammatory symptoms gradually subside, but a thin muco-purulent discharge continues, with some degree of heat and irritation about the urethra, and occasional smarting in passing urine. Under proper treatment, this usually subsides in the course of another fortnight or three weeks; but, if neglected, or in certain constitutions, it may last for any months, or even years, then degenerating into a *Gleet*. In proportion to the continuance of the affection the inflammatory symptoms subside, though the specific and contagious character does not disappear, and the infection may continue so long as the discharge keeps up. Hunter mentions the case of a girl who had been two years in the Magdalen Hospital, and who infected a person with whom she had connexion immediately after she left that institution. The persistence of the contagion of gleet is, it is true, more marked in women than in men. The long persistence of contagion is in accord with the fact that gonococci have been found in the urethral discharge many months or even several years after the commencement of the disease. The presence of the gonococcus may be taken as proof that the discharge is still infectious, but, on the other hand, failure to demonstrate the organism can hardly justify the Surgeon in pronouncing the patient free from any risk of causing infection. So long, indeed, as any discharge continues from the male urethra, though it be but a daily drop, the patient must be looked upon as infectious. The importance of this subject is obvious, and it seems certain that many inflammatory affections of the pelvic organs occurring in newly-married women are due to infection by an apparently insignificant urethral discharge in the husband.

The severity and the continuance of gonorrhœa are often opposed to one another. Thus the disease is most severe in young and plethoric persons, and in first attacks; but it is most difficult of cure in strumous constitutions, more especially if there be a gouty or rheumatic tendency co-existing, and it is very troublesome to remove after repeated attacks. I have observed repeatedly that it is very apt to degenerate into a gleet in people who are subject to chronic eczema.

There is a form of chronic gleet which continues very persistently after an attack of gonorrhœal epididymitis. In these cases the discharge is not so much urethral as testicular. It appears to proceed from the increased exudation from the mucous membrane of the secretory and efferent structures of the testis, during the process of resolution of the inflammation.

The length of time that the infection of gleet will continue in both sexes, but especially in the female, makes it somewhat difficult to say whether the poison of gonorrhœa can be generated *de novo*, as it is not improbable that many individuals communicate the disease, believing themselves to be perfectly cured, though still suffering from slight gleet.

Gleet.—The term *gleet* is applied to any mucous or muco-purulent discharge, which is very small in amount and persists for an indefinite time unaccompanied by any other obvious symptoms. This condition is one which gives rise to great mental uneasiness in many patients, and some varieties are, moreover, liable to terminate in stricture if unrelieved. The correct diagnosis of its nature and source is, therefore, of extreme importance. In the first place, it is necessary to remember that in young men a somewhat copious flow of mucus is apt to accompany an erection of the penis. When, as is frequently the case,

an erection occurs just before waking in the morning, the mucus may be found glueing the lips of the urethra together, and may be mistaken by the patient for a gleet. Again, true gonorrhoeal gleet must not be confounded with prostaticorrhoea (see p. 1140). Desormeaux has shown that a true gonorrhoeal gleet is due to the presence of chronically inflamed patches of mucous membrane in the urethra. These patches are purplish or dark red in colour, whereas the normal urethra is a pale pink. Sometimes the surface of the mucous membrane is covered with small granulations, like those seen on the conjunctiva in granular lids. This condition Desormeaux calls "*granular urethritis*." The patches may be multiple, but more often there is only one situated in the bulbous portion of the urethra. The *symptoms* of such a condition are the following: A slight, sometimes almost colourless, sometimes yellowish, discharge will be found glueing the lips of the urethra together in the morning. This discharge is little affected by diet or stimulants, but is usually greatly aggravated by connexion. If during micturition the first few drops of urine be passed into a separate vessel, flocculi of mucus and pus are seen floating in it. There is no pain or discomfort in micturition, but the stream may be slightly narrowed, and a few drops of urine may be retained in the urethra, and dribble away afterwards, as in a slight stricture.

In a large number of cases of gleet the chronic inflammatory patches in the mucous membrane are sufficient to cause actual narrowing, or rather diminished extensibility of the urethra; so constantly indeed is this the case that the presence of a chronic gleet may almost be said to indicate the existence of a stricture. In other cases the gleet may be due to a chronic inflammatory discharge from the glands and follicles of the urethra. Hill states that it occasionally arises from small vegetations or warts situated immediately inside the meatus; he also drew special attention to the important part played by a contracted meatus in causing the continuance of a chronic gleet.

In examining the urethra in a case of gleet, some information as to the condition of the canal may be obtained by the passage of an olive-headed bougie, meatotomy being, if necessary, performed to allow its introduction (p. 1198). If an inflamed spot be present, a slight feeling of resistance will be felt, and the patient will complain of pain as the bougie passes over it. On withdrawing the instrument a drop of blood may be found on its bulb.

In these cases the most reliable information is obtained by the use of the **Endoscope**. In its simplest form this consists of a metal tube about the size of a No. 12 or 14 catheter, down which light may be thrown with a mirror or by an electric lamp. The most convenient instrument is that made by Leiter of Vienna. It consists of a straight metal tube which is provided with an ebony obturator to facilitate its introduction into the urethra. The expanded ocular end of the instrument, which accurately fits into the tube, contains a small electric lamp the light of which is directed down the tube by means of a mirror. Before introducing the endoscope, 10 minims of a 10 per cent. solution of cocaine should be injected into the urethra with an L'tzmann's syringe. The endoscope is then passed downwards as far as the bulb, where the diseased condition which causes a chronic gleet is most commonly situated. Granular patches and other abnormal conditions of the mucous membrane are readily recognized by an experienced observer, and, moreover, local treatment can be carried out more accurately through the endoscope than in any other way.

Antal and Hurry Fenwick have found that distension of the penile urethra by the injection of air facilitates endoscopic examination. A special modification of Leiter's instrument has been constructed for this purpose.

The **Treatment of Gonorrhoea** must be conducted with reference to the stage of the disease, but especially with regard to the acuteness of the inflammation accompanying it.

It has been proposed to adopt what has been termed the *abortive* treatment, during the earliest stages of gonorrhoea ; indeed, during the *incubative* period. This method consists either in the injection of a very strong solution of the nitrate of silver into the urethra, or in the application to the inflamed mucous membrane of a strong ointment of that salt by means of a bougie smeared with it ; other Surgeons, again, have recommended the administration of very large doses of copaiba at this period. These various plans have, however, deservedly fallen into disrepute. I have on several occasions seen most intense inflammation produced by this mode of treatment, and never, in any case, any good result. Independently of this, it is impossible to know whether the case, in the earliest stage, will prove to be one of simple urethritis or a specific gonorrhoea.

In the *acute inflammatory stage*, attended by heat, swelling of the organ, great ardor urinæ, and abundant muco-purulent discharge, the activity of the treatment must be proportioned to the intensity of the inflammation. If this be severe, warm hip-baths, poppy fomentations, or the envelopment of the penis in warm water-dressing, will be of essential service. At the same time the urine must be diluted, and its acidity lessened, by the patient drinking large quantities of alkaline diluents—barley-water or linseed-tea containing carbonate of potassium in solution ; and the bowels may be kept in action by the administration of saline aperients. Twenty to thirty grains of carbonate of potassium or a drachm of citrate of potassium with twenty or thirty minims of tincture of hyoscyamus in an ounce of camphor water should be given every four or six hours. All alcoholic stimulants, spices, salt food, and coffee must be avoided, the diet being restricted to light slops, and perfect rest enjoined. By such means as these, the activity of the inflammation will be gradually lessened, the discharge becoming thinner, the smarting in micturition less severe, and the erections less painful. The patient should also be desired to pass his urine frequently, so as to wash the urethra clean.

During the acute inflammatory stage the application of local remedies to the urethra has, as a general rule, been found harmful, but since the nature of the virus has been recognized, the use of germicide injections and bougies has been tried with some degree of success. Watson Cheyne recommends the use of iodoform and eucalyptus bougies. These are composed of iodoform, 5 gr. ; oil of eucalyptus, 10 m ; oil of theobroma, 35 gr. This is sufficient to make one bougie 4 inches long. It is thus used : the patient first passes water to clean the urethra ; he then dips the bougie in carbolic oil (1 in 20) and passes it quickly into the urethra before it becomes softened by the heat of his fingers. It must be pushed in with a pencil, or some convenient instrument, till it completely disappears. An absorbent pad of iodoform or salicylic wool is then placed over the end of the penis, and covered with oiled-silk or gutta-percha tissue secured by a strip of plaster. The patient then refrains from making water as long as possible. One bougie may be used daily for two or three days, and in the interval some simple injection, such as

chloride of zinc (gr. $\frac{1}{6}$ to $\frac{3}{4}$), or sulpho-carbolate of zinc (gr. ij. to $\frac{3}{4}$.) may be used. Cheyne states that by these means the inflammation is often cut short and a cure effected in a week or ten days or sooner. If it fails it does no harm. One-twentieth of a grain of perchloride of mercury added to each bougie is said to increase the certainty of their action. In this stage also the use of strong injections of nitrate of silver has in some instances been followed by a rapid cure. Cotes, who gave this method of treatment a thorough trial at the Lock Hospital, proceeded as follows: An endoscope was introduced as far as the inflammation of the mucous membrane extended, this being often as much as four inches by the third day. The mucous membrane was then dried with wool mops. A wool mop soaked in a 10 grains to the ounce solution of silver nitrate was then passed down the tube with a stylet until it projected beyond the end. By withdrawing the endoscope and the stylet together, the nitrate of silver was brought into contact with the whole of the inflamed mucous membrane. A hot bath was given at night, and the patient kept in bed during the following day. A saline aperient and an alkaline mixture were prescribed, and a simple injection, such as weak Condyl's fluid, directed to be used several times daily. Cotes treated 42 cases in this way. In 40 in which the disease was of many days' duration, the average duration of the cure was twelve days; whilst 2 cases of only two days' duration were cured in two days.

During the second, or in fact in all stages of gonorrhoea, much harm is often done by applying lint to the penis. This does not absorb the discharge, but rather shuts it in. It is better to put the penis in a macintosh gonorrhoea-bag, at the bottom of which a good-sized piece of salicylic wool may be placed to absorb the discharge.

When the *third stage* of the disease has been reached, specific treatment may be employed with great advantage; while, if recourse were had to it at an earlier period, it would certainly increase the inflammation and give the patient much distress. Even in this stage the specific remedies, such as copaiba and cubebs, must be cautiously given; the Surgeon feeling his way with them, and being prepared to discontinue them if he find that they increase the irritation. Should the disease, however, from the commencement, have assumed a subacute character, the specific treatment may with safety be adopted at a much earlier period.

Copaiba and cubebs are extensively used in this stage of gonorrhoea. Of these, copaiba is the less irritating, and consequently more generally to be preferred. It may be administered in a variety of ways: in capsule, pill, draught, or extract. The capsule is generally to be preferred, on account of the nauseous taste being thus more completely disguised; but in many cases it acts with more certainty, and with better effect, if given in either of the other forms. When the capsules are given, the patient may take from six to eight or ten in the day, and should at the same time have an alkaline mixture, which increases materially the effect of the drug. A very excellent mode of administering copaiba is to rub it down into a mass with burnt magnesia, and to let the patient take about a drachm of this paste three times a day, in a bolus wrapped in wafer-paper; or, if the taste be not much objected to, he may take it most advantageously in mucilage, with liquor potassæ and tincture of hyoscyamus.

In some relaxed constitutions, and more particularly after frequent claps,

cubebs will be found to cure the patient more readily than copaiba, or rather more successfully if given in combination with it. An excellent plan is to put about half an ounce of powdered cubebs into a mortar, and to rub it up with as much copaiba as will form a stiff paste, of which the patient should take a drachm as a bolus thrice daily. The effects of this electuary are often most striking ; but it can be used only in the constitutions indicated, and after the more active inflammatory symptoms have subsided. Copaiba in many subjects brings out a red, raised rash, most marked on the backs of the hands and feet, but sometimes extending over the whole body. It is accompanied by considerable itching and often by some rise of temperature. Hill states that a similar eruption, but more papular in character, may follow the administration of cubebs. Hæmaturia has occasionally been observed as the result of large doses of copaiba. Oil of yellow sandal wood may sometimes be employed with advantage, though its action is somewhat uncertain. It may be given in capsules in doses not exceeding twenty minims three times a day, or the following formula will be found useful : oil of sandal wood, ʒij., tragacanth in powder ʒss., water to ʒviiij. ; one ounce to be taken three times a day.

It is during the third stage of gonorrhœa that **Injections** may advantageously be used. Much and very unfounded prejudice exists against their use in the minds of many ; but surely it is as safe to apply proper local applications to an inflamed urethra as it is to an inflamed conjunctiva ; and the bad consequences, such as stricture and inflamed testicle, which have sometimes been referred to their use, have either been due rather to the long continuance and to the severity of the disease itself than to the remedies employed, or to their application at too early a stage or of too great a strength. It is in long-standing cases of gonorrhœa, in which the discharge continues for months or years, that stricture follows, not in cases of ordinary duration ; and it is the result of the chronic inflammatory thickening of the mucons membrane, and has no more to do with the injections than with the copaiba or salines which the patient may have taken. As the ardor urinæ subsides, emollient and slightly astringent injections may be used. Perhaps the best is permanganate of zinc in the strength of one, or rarely two, grains to eight ounces of distilled water. Berkeley Hill found this injection very free from irritating properties, and most useful except in very chronic cases ; of 70 cases in which he used it, 10 were cured and 54 much improved, in 4 it had no effect, and in 2 it increased the discharge. Chloride of zinc (gr. $\frac{1}{8}$ to the ʒi.) and sulpho-carbolate of zinc (gr. ij. to the ʒi.) are often useful. Extract of opium or extract of belladonna is frequently added to urethral injections to allay the irritation which they are apt to cause. The permanganate should, however, always be used alone, as it forms an almost explosive mixture with some vegetable extracts. As the disease subsides, a stronger astringent is required, and then one or two grains of the acetate of zinc may be added to each ounce of the injection ; or a weak solution of the sulphate may be employed, gr. ij. to each ounce of water. In the later stages Hill found the sulphates of zinc, alumina, copper, and iron very useful. He frequently prescribed them together, thus : sulphate of zinc 30 to 40 grains, alum 30 to 40 grains, sulphate of iron 20 grains, and sulphate of copper 2 grains, in eight ounces of water. During the whole of this stage, the diet and habits of life must be carefully regulated, and all stimulants interdicted. The injections should be discontinued as soon as the discharge has ceased ; unless this be done, they may re-induce it.

The mode of injection is of importance. A glass syringe should always be used, with a smooth rounded nozzle. The patient sitting on the edge of the chair and holding up the penis, should carefully insert the end of the syringe between the lips of the urethra, and then slowly throw in the injection as far as it will go. Although the inflammation is usually at first confined to the anterior portion of the urethra, yet it in most cases extends to the bulb, and the injection should be applied to the whole length of the inflamed mucous membrane. If any enter the bladder this is of no consequence, as it will immediately be decomposed by the salts and mucus of the urine.

Instead of the ordinary glass syringe, the injector (Fig. 908) may advantageously be used. By it, the injection is thrown from behind forwards, so that when passed beyond the inflamed part it washes out the discharge, instead of forcing it further on.

Treatment of Gleet.—In gleet, much difficulty will often be experienced in curing the patient of his discharge. Here much depends not only on the administration of proper remedies, but on care being taken to regulate his habits of life. It will constantly be found that, after the disease has apparently been cured, excesses at table, and more especially the drinking of beer, or of effervescing or acid wines, will bring back the discharge. It will return also after connexion, though it have previously ceased entirely. This is especially the case in strumous, gouty, or rheumatic subjects, in whom all urethral inflammations are with difficulty removed. In these cases, then, abstinence from alcoholic liquids and dietetic stimulants, and a continent life must be strictly enjoined; but the local treatment requires careful attention.

In the early stages of gleet an attempt may be made to cure it by injections. For this purpose somewhat stronger solutions are required than in the more acute period of the disease. Sulphate of copper will often be found useful, commencing with half a grain to the ounce, and gradually increasing it to one or even two grains.

Fig. 908.—Teevan's injector.

Tannic acid in the strength of from two to four grains to the ounce will sometimes check the discharge. Soluble bougies, similar to those already described, but containing tannic acid, sulphate of zinc, or acetate of lead, are often of great service. These, combined with the internal administration of copaiba and cubebs, or the perchloride of iron, may effect a cure. If these do not succeed, the occasional passage of a full-sized bougie is of the greatest use. If the orifice of the urethra be small meatotomy should be the first step in the treatment. The meatus must also be examined for warty growths, which may keep up the discharge.

When the disease has become very chronic, and has assumed the form of granular urethritis, it is difficult of cure; for, as Desormeaux pointed out, no injection, which the healthy portion of the urethra is capable of bearing, will have much effect upon the inflamed patch. He therefore recommended the application of a strong solution of nitrate of silver through the endoscope.

This treatment has proved most satisfactory. The granular patches are dried with small wool mops and are then touched with a mop soaked in a solution of nitrate of silver, 10 to 20 grains to the ounce, according to the amount of congestion. In the absence of the endoscope the solution may be applied by means of Guyon's injector (Fig. 909). This consists of a hollow bulbous sound perforated in the bulb, and fitted with a small syringe. The bulbous sound having been passed down the urethra till the exact situation of the inflamed spot is found by the tenderness and slight cling before mentioned, the perforated head is held fixed at the diseased spot, and a few drops of a solution of nitrate of silver (ten to twenty grains to the ounce of water) are injected. The patient should pass urine immediately before the injection, and not again for some hours if possible. Berkeley Hill, who had great experience of this mode of treatment, states that, if the patient keep quiet for some time after, no complications are likely to follow ; but neglect of these precautions may be followed by swelled testicle or even perinæal abscess. After the operation a mixture containing citrate of potassium and hyoscyamus should be prescribed and a weak astringent injection should be used between the different sittings, of which several may be required. The passage of bougies for a short time is usually necessary to complete the cure. Otis, of New York, is of opinion that every prolonged gleet is the result of a

Fig. 909.—Guyon's Injector. The Smaller Figure represents the Nozzle.

narrowing of the canal, and he recommends internal urethrotomy as a cure—cutting the urethra up to its normal size by the method described under the treatment of stricture of the urethra. The operation is somewhat severe, and should never be resorted to till all other means have failed.

The treatment of gleet may therefore be summed up as follows : The patient must be carefully examined, in order to detect, if possible, some constitutional condition, such as struma, gout, or rheumatism, which may serve as a guide to general treatment, diet, and use of stimulants. Change of air and sea-bathing are often of essential service. The orifice of the urethra must be enlarged, if necessary. Warty growths or suppurating follicles at the orifice may be touched with nitrate of silver. If they are not found, the electuary of cubebs and copaiba, or one composed of cubebs and the sesquioxide of iron, may be administered with advantage, and the injections recommended for the chronic stage of gonorrhœa may be persevered with. Should these fail, and should the olive-headed sound give distinct evidence of a tender spot, and perhaps a slight narrowing of the urethra, the passage of a full-sized metallic bougie every second or third day should be tried. If, after a fair trial, this also fail, the application of nitrate of silver, by means of the endoscope, or with Guyon's injector, must next be had recourse to, followed by mild injections and the passage of bougies ; and, lastly, if everything else have failed, and a distinct narrowing of the canal be present, internal urethrotomy may be tried as a last resource.

Complications of Gonorrhœa.—Gonorrhœa, when acute or virulent, seldom runs its course without local complications of some kind, the result of the propagation of the inflammation to neighbouring parts, often of considerable severity, and occasionally even hazardous to life :—such as chordee, phimosis, sympathetic bubo, perinæal abscess, irritability of the bladder, retention of urine, hæmorrhage from the urethra, &c. Many of these complications present no special features, but require to be treated on general principles, without reference to their specific cause. Others demand more special management, and these we may briefly consider here.

Inflammation of the Lymphatics of the Penis may occur, stretching along the sides and dorsum of the penis in the form of hard threadlike lines, with much redness and œdema of the integuments, and general swelling of the organ, the glans in these cases often assuming a turgid aspect and a dull brick-red colour. This condition is a very serious one, as it may lead to one of two consequences, or both may ensue, viz., inflammation and suppuration of the inguinal glands, or blood-poisoning. It is the latter result that gives rise to the most serious constitutional effects in gonorrhœa, closely resembling the less severe forms of pyæmia.

Chordee, or painful erection of the penis, with twist of the organ, coming on at night, is often a most distressing and troublesome symptom. It is usually best relieved by the application of cold to the part, and the administration at bedtime of a pill composed of gr. j. of opium with gr. v. of camphor. Ricord recommends a suppository of camphor and opium, gr. x. of camphor and gr. j. of the watery extract of opium, to be introduced into the rectum an hour before bedtime, as the best means of removing the tendency to chordee. Full doses of bromide of potassium are sometimes of use.

Acute Prostatitis, presenting all the symptoms described on p. 1138, and in rare cases terminating in abscess, is an occasional complication. It must be treated as there described.

Chronic Prostatitis is rather a sequel of gonorrhœa than a complication. Its symptoms and treatment have already been described (p. 1139).

Inflammation of the Neck of the Bladder with Strangury and Dysuria is not an uncommon complication. It arises from exposure to cold or wet during a clap, and occasionally from the use of too strong injections. The discharge may become less when the symptoms of the deeper inflammation set in. When the neck of the bladder only is inflamed, the urine remains acid, and contains but a slight excess of mucus. Frequency of micturition, often excessive, and accompanied by the most severe pain, forms the most prominent symptom. Pus and blood may escape with the last few drops of urine. It is distinguished from acute prostatitis by rectal examination, when absence of prostatic swelling and tenderness will be recognized. The inflammation in many cases is less acute, especially when it comes on in the third or fourth week of the clap. In the acute form leeches to the perinæum, hot baths and fomentations, and full doses of Dover's powder, or of hyoscyamus and potash, will afford much relief. If the pain is very severe, a morphia suppository must be inserted into the rectum. In more chronic cases the administration of the perchloride of iron, with belladonna suppositories, will be beneficial.

Cystitis, of an acute character, may occur by the extension of the urethral inflammation. The urethral discharge diminishes as the symptoms of cystitis come on, or ceases, as in epididymitis ; the patient is seized with intolerable

and frequent dysuria, strangury, and general febrile disturbance. The urine becomes loaded with muco-pus, and may be fetid and alkaline. The condition is perilous. There is danger to life if the constitution be broken, and there is always danger of prolonged or possibly intractable subacute cystitis. Indeed, I believe that many of the cases of chronic cystitis, with muco-pus in the urine, and perhaps atony of the bladder occurring in middle-aged men, may be traced back to the influence of a gonorrhoea contracted in early life. The *Treatment* of this condition consists in the employment of belladonna or opiate suppositories; the frequent use of warm hip-baths; the application of fomentations to the perinæum and hot poultices to the pubic region. The free administration of opium is often of great use, and an occasional dose of calomel should be given to relieve the bowels. As the cystitis subsides, the urethral discharge reappears.

Pyelitis and **Nephritis** are very rare complications of gonorrhoea. Murchison has recorded two cases in which death rapidly followed extension to the kidney, with coma and delirium. In a case lately in University College Hospital, a slight urethral discharge was followed by pain in the course of the ureter, and the symptoms of pyelitis. The disease assumed a chronic form, the pus in the urine being very abundant. Gonorrhoeal rheumatism of a severe form set in at the same time. After about two years the patient partially regained health, the amount of pus becoming very small. In another case, a large renal abscess formed some time after an attack of gonorrhoea, to which it seemed to be directly attributable. The abscess was aspirated twice, and the patient recovered, but at his death some years after, the kidney was found to be shrivelled to a small mass of fibrous tissue.

Retention of Urine from Gonorrhoea may set in at any period of the acute stage. The obstruction is usually dependent on congestion and inflammation of the mucous membrane of the urethra. Leeches to the perinæum, the warm hip-bath, and opiate suppositories, will probably afford relief. It is always desirable to avoid using the catheter, as it is apt to lacerate the inflamed mucous membrane, and thus to occasion troublesome bleeding; and it will always produce much pain, and increased irritation of the canal. Should, however, the retention not give way to the means above indicated, it will be necessary very carefully to introduce a full-sized instrument, which will enter the bladder as easily as a smaller one and with less risk of injury to the tender walls of the canal. If an old stricture complicates the acute gonorrhoea the difficulty in passing a catheter may be very great. When the catheter has been introduced, it is often somewhat difficult to determine whether it should be left in or taken out. If it be left in, inflammation is increased; if it be taken out, the Surgeon may not be able easily to introduce it again. If, therefore, it have been introduced without much difficulty, it is better to withdraw it after the bladder has been emptied; but if, on the other hand, the catheter have been passed with great difficulty, and be firmly grasped by spasm, it should be left in.

It must be remembered that the retention may be due to more serious conditions: to prostatitis, to abscess in the prostate or the perinæum, or to inflammatory exudation in the tissues about the neck of the bladder. In these circumstances, active measures will be required, with the use of the catheter twice in the twenty-four hours, and probably free incisions into the perinæum, if there be pus or urine extravasated into that region.

Hæmorrhage from the Urethra may occur either as the result of chordee,

and consequent rupture of some blood-vessels of the corpus spongiosum, as the consequence of attempts at passing the catheter, or as a simple oozing from the inflamed mucous membrane. Most commonly it may be arrested by the application of ice. If it be apparently due to intense inflammatory hyperæmia leeches may be applied externally followed by hot fomentations. Should it be abundant, the introduction of a large gum-elastic catheter, and pressure by means of a bandage to the penis or perinæum, will arrest it.

Urethral or Peri-Urethral Abscess occasionally forms in gonorrhœa. It is supposed to result from inflammation culminating in suppuration, taking place in one of the lacunæ or glands of the mucous membrane. An abscess may form at any part of the urethra, but the two most common situations are near the end of the penis and in the region of the bulb. It is possible that in many cases the pus may be discharged into the urethra without being recognized; but if the collection of pus reaches any size it points towards the surface. In the neighbourhood of the glans it forms a rounded swelling, usually projecting under or to one side of the frænum. It is tender on pressure, and the parts round are swollen and œdematous. It should be opened as early as possible lest it burst into the urethra, after which, as the aperture is usually insufficient to drain the cavity, a second opening will form on the surface, leaving a fistula, which is very troublesome to heal.

When the abscess is situated in the region of the bulb, it forms a hard, tender swelling in the perinæum, constituting one of the varieties of *perinæal abscess*. In this situation, also, if opened early by a free incision in the middle line, it will be found to have no communication with the urethra, and will quickly heal without leaving a fistula. If it be not opened in time, it may burrow widely beneath the accelerator urinæ, and the expansion from it covering the penis. Under these circumstances it may be felt both at the root of the penis and in the perinæum, and there may be considerable swelling of the scrotum. The incision in such a case should be made behind the scrotum only. If left too long, a communication with the urethra may have taken place, but provided the incision is made in the perinæum only, it will heal without difficulty.

Sequences of Gonorrhœa.—The sequences, or more remote complications of gonorrhœa, are partly local and partly constitutional. Amongst the local we find more particularly **Warts** about the prepuce and glans or within the urethral orifice, which require to be treated by excision or caustics; and **Stricture**, the management of which is fully described elsewhere. In some cases, also, in consequence of extravasation of blood, or inflammatory exudation into the corpus spongiosum or the corpora cavernosa, limited and localized **Induration and Thickening of the Penis** may result, attended by chordee, painful erections, and a permanent twist in the organ. In such conditions as these, an attempt may be made to produce absorption of the effused mass, by the administration of small doses of perchloride of mercury, with the inunction of iodide of lead ointment.

After the cure of a clap that has been of long continuance, the generative organs are often left in a *weak and irritable state*; the penis, scrotum, and spermatic cords being lax and elongated, often with painful and dragging sensations about the cords and groins.

Besides the strictly local complications of gonorrhœa, certain sequences, to which some constitutions are especially liable, occasionally occur as the result

Of this disease; viz., inflammation of the testes and of the eyes, and rheumatism. Some of these, as the affections of the eyes and testes, may be either local or constitutional; the others are clearly constitutional. The constitutional effects of gonorrhœa offer characters that have some analogy to those presented by the chronic and subacute forms of pyæmia. This is more especially the case in monarthritic inflammation of the knee or wrist, leading to disorganization or permanent ankylosis of the joint.

Gonorrhœal Epididymitis is certainly the most common of these sequences. It almost invariably affects only one testis, and commences in the epididymis, whence it extends to the body of the organ. It usually occurs in individuals who have a lax and long scrotum, with very pendulous testes. It seldom sets in before the third week after the occurrence of gonorrhœa, but may occur at any period during the continuance of the discharge, though it is more frequent between the fifth and sixth weeks than at any other time. In cases of gleet, also, it not uncommonly occurs at a later period. In many instances it is referred to some slight injury—a blow, or squeeze, received during the continuance of the gonorrhœa; but in some cases it would appear to arise from extension of the inflammation along the ejaculatory duct. It was formerly believed to arise in some cases from so-called metastasis of inflammation from the urethra to the testis. That the disease commences in the epididymis, may be advanced in support of the first opinion; whilst the fact that the discharge usually ceases when the inflammation of the testicle comes on, and returns as it subsides, has been adduced in support of the doctrine of its metastatic origin. Curling was of opinion that the diminution of discharge is due to counter-irritation, as he had seen a case in which the urethral discharge ceased, although the orchitis had been occasioned by a blow. As the symptoms and treatment of gonorrhœal inflammation of the testicle present nothing peculiar, I shall reserve their consideration until I come to speak of diseases of this organ. Gonorrhœal epididymitis is apt to be followed by long-continued gleet, consequent on the exudation from the lining membranes of the vas deferens, and the secretory apparatus of the testes.

Gonorrhœal Inflammation of the Vesiculæ Seminales is probably more common than is generally supposed, for as Jordan Lloyd, who has drawn special attention to this complication, has pointed out, its symptoms closely resemble those of prostatitis. These are painful and frequent micturition, painful defæcation, with occasionally painful emissions and priapism. On rectal examination the vesiculæ are felt as elongated swellings above the prostate. The inflammation of these bodies is no doubt due to direct extension from the urethra. The *Treatment* is the same as for acute prostatitis.

Gonorrhœal Inflammation of the Eyes is fortunately not of very common occurrence. It may affect either the conjunctiva or the sclerotic.

Gonorrhœal Conjunctivitis is one of the most destructive forms of purulent ophthalmia, giving rise not unfrequently, in the course of forty-eight hours, to the most intense chemosis, with opacity and softening of the cornea, followed by staphyloma and escape of the aqueous humour. It results from direct infection of the conjunctival sac with the gonorrhœal discharge. In the majority of instances only one eye is affected; but, in some, both are involved to an equal extent. The disease commences with the ordinary symptoms of conjunctival inflammation; itching and swelling of the eyelids, velvety redness of the conjunctiva, muco-purulent discharge, with much

lachrymation. The chemosis sets in early, and is very severe ; and, unless treatment afford speedy relief, the consequences are most disastrous to vision.

Treatment.—The prevention of purulent ophthalmia in new-born children as the result of infection by the vaginal discharges of the mother, should consist in the use of a vaginal douche of 1 in 2000 perchloride of mercury. As soon as possible after birth the child's eyes should be washed with weak boric lotion, and a few drops of a 2 per cent. solution of nitrate of silver introduced into the conjunctival sac, as recommended by Cr  d  . For the relief of gonorrh  al ophthalmia active measures are required. The patient must be confined to a dark room, the bowels must be kept regular, and a moderate diet allowed ; much relief may be given by the extraction of a small amount of blood from the temple by leeches. The most useful topical agent that we possess is the nitrate of silver. This should be freely applied with a camel's-hair pencil in the strength of 15 or 20 grains to the ounce of distilled water, and the eye then washed out with weak salt solution. The conjunctiva may be rendered insensible by cocaine before the application. The lids should be kept covered by compresses dipped in weak alum lotion, and the purulent discharge, as it accumulates, carefully washed away by tepid alum injections. Instead of alum, boric acid may be used with great effect, and lately, a very weak solution of perchloride of mercury (1 in 5000) has been tried with considerable success. In doing this, great care must be taken that none of the discharge come into contact with the eyes of the Surgeon or nurses, as it is highly contagious, and will almost to a certainty produce the disease ; instances are recorded in which, in this way, the attendant's vision has been destroyed. If the chemosis be considerable, the swelling must be incised ; and, as the inflammation subsides, belladonna lotions may be employed with advantage, and the use of the nitrate of silver and other lotions gradually discontinued.

Great care must be taken to prevent infection of the other eye when only one is affected. It may be covered with a compress, or a watch-glass may be placed over it and secured by plaster or collodion.

Gonorrh  al Scleritis is by no means of such frequent occurrence as the conjunctival inflammation ; when it happens, it will be found to be associated with gonorrh  al rheumatism, and not unfrequently with inflammation of the testicle, occurring apparently in individuals in whom there is a tendency to affection of the fibrous tissues. This disease is evidently of constitutional origin, as it cannot possibly arise from local contagion ; it is attended with the ordinary signs of sclerotic inflammation, and is usually accompanied by some degree of iritis.

The constitutional *Treatment* is that for gonorrh  al rheumatism. Locally the eye must be protected from light, and a few drops of atropine solution put in occasionally. If there is much pain, blood may be taken from the temple by cupping or leeches.

Gonorrh  al Inflammation of the Nose, attended with profuse suppuration, the result of direct infection, is a complication that I have more than once had occasion to observe. The swelling of the organ is considerable, the tenderness great, and the discharge abundant ; a condition, indeed, of the Schneiderian membrane that seems analogous to the inflammation of the conjunctiva just described. The *Treatment* that I have found to succeed best, consists in fomentations, followed by astringent lotions or injections.

Gonorrhœal Inflammation of the Rectum has already been described at p. 952.

Gonorrhœal Rheumatism principally occurs in young and otherwise healthy persons. The exact nature of the disease is very uncertain. It is supposed by many to be a form of blood-poisoning analogous to pyæmia. Kammerer is said to have found the gonococcus in the fluid of a knee-joint affected with gonorrhœal rheumatism, but this observation has not been confirmed by others. Berkeley Hill states that his observations led him to believe that the disease is met with chiefly in gouty or rheumatic subjects. If the patient have not previously suffered from these affections, a family history indicating a tendency to them will usually be found. In patients who are distinctly rheumatic or gouty, Hutchinson states that any urethral discharge, whether specific or not, may give rise to symptoms identical with those of gonorrhœal rheumatism. The affection is more common in men than in women, and seldom sets in till the third week after the commencement of the discharge, though it may occur as late as the second month. The disease may assume various forms. It may commence insidiously with pain in the joints, quickly followed by considerable effusion. Several joints may be affected, but the knee is attacked with far greater frequency than any other articulation. The febrile disturbance may be slight. The pain and swelling last usually for some weeks, and gradually subside; but relapses are common. In other cases the course of the affection more closely resembles that of acute arthritis; the pain is intense, and the ligaments are early affected. The swelling assumes an oval form, effusion into the articular cavity being slight, or even wanting. The constitutional disturbance is severe. This variety most commonly ends in ankylosis. In another form occasionally met with, pain forms the chief symptom, without swelling or interference with movement. Other structures beside the joints may be affected, as the fasciæ, the sheaths of tendons, bursæ, and occasionally the nerves. Gonorrhœal scleritis, as already mentioned, is always connected with rheumatism, and orchitis may arise from the same cause. Gonorrhœal may be distinguished from simple acute rheumatism by the attack being less severe, by the affection usually being limited to two or three joints, and often to the knee only, and by the absence of the profuse sweating and the creamy-white tongue. The prognosis is, as a rule, good. Suppuration may occasionally take place, and the disease then merges into that immediately to be described, gonorrhœal pyæmia. Ankylosis is, however, very common, especially in the arthritic form. This arises not so much from destruction of the cartilages, as from shortening and contraction of the inflamed capsule of the joint when recovery takes place. This form of ankylosis is practically incurable.

Treatment.—The first essential point of treatment is to check the urethral discharge as quickly as possible by the means already described. Iodide of potassium, with alkaline tonics, are sometimes of use. Salicylate of sodium in large doses has been tried with varying effect. Quinine may be given if the temperature is elevated, and in the later stages perchloride of iron is often of material service. The local joint-affection must be treated by absolute rest on splints, blistering, and strapping over mercurial ointment in the later stages. If ankylosis occurs, it must be treated as described on p. 363.

Gonorrhœal Pyæmia.—It is not easy to draw a clear distinction between gonorrhœal rheumatism and pyæmia. The term “pyæmia” is applied to those aggravated cases, fortunately of very rare occurrence, in which the joint-affec-

tion terminates in suppuration, with complete destruction of the articulation. In these cases abscesses are not uncommonly met with in other parts of the body, especially in the subcutaneous tissue. Visceral abscesses are of very rare occurrence. The symptoms are those of chronic pyæmia (Vol. I., p. 985).

Cutaneous Eruptions, chiefly consisting of roseola, with slight pityriasis and perhaps a few patches of psoriasis, have been described as occurring occasionally in severe cases of gonorrhœa. The description given by Travers of these eruptions makes them correspond so closely to the early manifestations of syphilis that it is probable that they really resulted from an intra-urethral chancre, mistaken for gonorrhœa. If these cases and those in which the rash arises from copaiba or cubebs be excluded, it is doubtful if any true gonorrhœal skin eruptions exist.

Gonorrhœa in the Female differs from the same affection in the male in being less severe in its initial manifestations but usually more extensive, of longer duration, and more apt to be followed by dangerous or even fatal sequelæ. The severity is less, on account of the shortness of the female urethra preventing the occurrence of the retention of urine as in the male, and also from the absence of such parts as the prostate, testes, &c., the implication of which constitutes the principal source of difficulty in men. Gonorrhœa in the female may affect the parts to very different degrees: thus, the vulva alone may be implicated, or, as most commonly happens, the inflammation may spread to the whole of the mucous membrane of the vagina. Bartholin's glands are frequently affected and may suppurate. The urethra is less commonly the seat of disease, though occasionally implicated with other parts: and, lastly, the interior of the uterus may become affected by the specific inflammation. In some cases it will even spread along the Fallopian tubes to the ovaries; and ovaritis, purulent salpingitis, and fatal peritonitis may thus be induced. In other cases dilatation of the tube and the formation of a pyosalpinx may occur; this is attended with the danger of rupture and the production of peritonitis.

The **Symptoms** of gonorrhœa in women are sufficiently well marked in the early stages, when there is an abundant muco-purulent discharge from the parts affected, with a good deal of inflammatory irritation, accompanied by pain in micturition, and a frequent desire to pass urine. As the disease becomes chronic, however, it is more difficult to determine its true character: it being apt to be confounded with some of those accidental and leucorrhœal discharges to which females of all ages are subject.

Diagnosis.—In the majority of cases, gonorrhœa may be distinguished from all other *muco-purulent discharges* of the female organs, by the presence of inflammation about the external parts, and the mucous membrane of the vagina and urethra. In these cases it will be found, on introducing a speculum (which, however, occasions considerable pain, and is firmly grasped by the contraction of the vagina), that the discharge comes from the vaginal wall, and that the uterine orifice is free from it, or nearly so; whereas in leucorrhœa the discharge proceeds in a great measure from the interior of the uterus, the os and cervix of which will probably also present signs of disease. It must, however, be borne in mind that the discharge in gonorrhœa may occasionally be in a great degree uterine; and that that of leucorrhœa may be an exudation from the mucous membrane of the vagina. In such circumstances, when the disease is chronic, it is almost impossible to arrive at a correct conclusion as to the nature of the case from simple inspection; and in these cases

of doubt the Surgeon had better give a very guarded opinion, lest he be led into the error of inculcating an innocent woman. The difficulty is increased, and a good deal of obscurity thrown over the case, by the fact that leucorrhœal discharges will occasionally give rise to urethritis closely simulating gonorrhœa in the male. Female *Children* also are occasionally subject to an acute inflammation of the vagina and nymphæ as the result of simple irritation, of constitutional disturbance, or of teething ; these cases require to be recognized, as they have frequently been the basis of unfounded accusations.

The **Treatment** of gonorrhœa in the female must vary, according as the disease is acute or chronic. In the acute stage salines, low diet, rest in bed, and emollient sedative fomentations, are the chief means to be adopted. As the disease subsides into a chronic condition, astringent injections must be employed ; a weak solution of acetate of lead or alum being especially useful. These injections should be employed three or four times a day and in large quantity. After they have been thrown up, a piece of lint well soaked in the lotion should be introduced between the opposed mucous surfaces, so as to prevent their coming into apposition, the discharge being in a great measure kept up by their friction against one another. In order that the injection may be properly given, the woman should lie flat on her back, and introduce the fluid with a syringe or irrigator. In the treatment of gonorrhœa in women, specifics are of no use unless the urethra be affected, when copaiba may very rarely be required. The disease is apt to degenerate into a chronic gleet condition, leaving a thin muco-puriform discharge, which will continue to be infectious for a great length of time. It is, therefore, most important not to relinquish the treatment until this is entirely cured, and the condition of Bartholin's glands must particularly be observed, as the discharge from these may continue to be infectious after other parts are cured.

STRICTURE OF THE URETHRA.

The existence of muscular tissue in the wall of the urethra is an anatomical fact which has an important bearing upon certain phenomena presented by some forms of stricture of the canal. The arrangement of the muscular tissue was shown by Hancock to be as follows :—The fibres of the inner layer of the muscular coat of the bladder pass forwards underneath the mucous membrane of the prostatic portion of the urethra, and those from the outer layer of the muscular coat of the bladder outside the prostate. These two layers join at the membranous portion of the urethra, forming the muscular covering of this portion of the canal. At the bulb, these two layers divide again ; the inner lying underneath the mucous membrane, separated from it merely by areolar tissue ; the external lying outside the corpus spongiosum, between it and its fibrous investment. At the anterior extremity of the urethra they unite again and form its lips. Thus the urethra is surrounded through its whole length by muscular fibres, a double layer of which invests it at the membranous portion, and again at the external meatus. The prostate and corpus spongiosum are included between planes of these fibres. The vesicles and ducts of the prostate are surrounded by layers of involuntary fibres ; those of the ejaculatory ducts coming from the non-striated layer of the vas deferens. These fibres are totally distinct from the common muscular apparatus of the perinæum ; and their existence proves the urethra to be a musculo-membranous canal.

By **Stricture of the Urethra** is meant a narrowing of the canal at one or more points. These may proceed from three distinct conditions: 1, Spasmodic Action of the involuntary Muscular Fibres situated outside the mucous membrane; 2, Congestion of the Mucous Membrane of the canal; or, 3, Organic Changes in the Mucous and Submucous Tissues, consisting of thickening, induration, or the deposit of plastic matter within them. According as the disease arises from one or other of these causes, it is termed a *Spasmodic*, a *Congestive*, or an *Organic* stricture. These different forms of stricture, which in practice are often associated, present so much variety in their symptoms, in the treatment they require, and the constitutions in which they occur, as to require separate description.

SPASMODIC STRICTURE.—The possession of muscular contractility by the urethra is obvious from the fact that a bougie may occasionally be introduced with sufficient ease, but that the Surgeon, on attempting to withdraw it, will find it tightly grasped; so, also, occasionally, on introducing the instrument, he will feel it meet with an obstruction, which on steady pressure will yield with that species of quivering which is peculiar to muscular spasm. Again, the fact that a patient will at one time pass his urine with the most perfect freedom, whilst, if it be rendered acrid or acid by drinking spirits, effervescent wines, or other similar beverages, almost complete obstruction will ensue, tends to prove the existence of an occasional spasmodic constriction of the canal. The effect of anæsthetics in facilitating the passage of a catheter must also be attributed to relaxation of spasm.

The **Causes** of spasmodic stricture are generally such conditions as occasion an irritable state of system, as long residence in hot climates, especially if conjoined with habitual excesses in drinking, high living and sexual indulgences. The more immediate causes are usually any circumstances that occasion irritation of the urethral mucous membrane, and thus give rise to spasm of the smooth muscular fibres beneath it. The most usual of these are those conditions of the system in which the urates are largely eliminated: as exposure to cold and wet, by which the action of the skin is suspended; or too free an indulgence in spirituous and acid liquors—such as red or effervescent wines, beer, or punch.

Symptoms.—In spasmodic stricture we find evidence of narrowing of the urethra, and consequent impediment to the free flow of urine, rapidly supervening under the influence of certain causes, and as speedily subsiding. A patient, for instance, in his ordinary health and passing urine freely, if he take such food or drink as will give rise to a very acid condition of this fluid, if he be exposed to cold, or get out of health in any way, suddenly finds himself able to pass his urine only in a small stream by drops with much straining, or may even be seized with complete retention. Under appropriate treatment these symptoms rapidly subside; recurring, however, on the application of any exciting cause. At the time of the occurrence of this spasm there is a sensation of weight and uneasiness in the perinæum, with evident irritation of the urethral mucous membrane, as shown by reddening of the lips of the orifice; in fact, spasm alone without congestion or the presence of some organic narrowing will never cause actual retention.

Treatment.—If the patient be suffering from spasmodic difficulty in passing urine, an injection, consisting of half a drachm of laudanum in a little starch, should be thrown up the rectum, a morphia suppository given, or a full dose of Dover's powder administered, and the warm hip-bath used.

As the opium begins to take effect, the urine will usually be passed without much difficulty. The bowels should then be made to act, when the patient will usually be relieved. If the spasm continue, as it often does, for some days or weeks after this, a full-sized soft bougie should be introduced every second or third day, in order to lessen the irritability of the urethra. In some cases this is more effectually done by the use of a steel bougie well warmed and oiled. Whatever instrument is used should be of large size, from No. 8 to 10. A small bougie will often be arrested, and will create much irritation, when a large one will pass readily. If the use of the instrument cause irritation and increase the spasm, it is better to omit it entirely, and to trust to constitutional treatment. But the Surgeon must not be discouraged, if the first few introductions of the bougie appear to increase the irritation; as the urethra becomes accustomed to the use of the instrument, relaxation of the spasm will take place. At the same time, the patient's general health should be carefully attended to; the bowels must be kept open, and the diet regulated; all acids, stimulants, and sweets being carefully avoided. During the time that the bougie is being used, he should take citrate of potash well diluted.

As a *preventive treatment* of these attacks, a careful regulation of the diet, warm clothing with the use of flannel, and keeping the skin in action by means of horsehair-gloves and tepid baths, will be found serviceable.

CONGESTIVE STRICTURE.—There can be no doubt that the two conditions of congestion and spasm are frequently associated in the urethra, in the relation of cause and effect; and this is the most frequent condition in which spasmodic strictures are found. Indeed, congestion plays an important part in all forms of stricture; it may, as we have just seen, be connected with the spasmodic variety; it may occur alone; or it may be associated with organic stricture. Some parts of the urethra appear to be more subject to congestion than others: thus, for instance, the membranous and prostatic portions, especially the folds of mucous membrane constituting the verumontanum, are peculiarly liable to become congested.

Causes.—Congestive stricture frequently occurs as the result of chronic and long-continued inflammation of the urethra, or of the passage of concentrated urine containing an undue proportion of urates. It is especially in gouty or rheumatic subjects who suffer from irritability of the skin and mucous membranes that this condition occurs. In these cases there is no permanent obstruction; but the disease is transitory, and due solely to a swollen state of the membrane of the part. In the majority of cases, however, it complicates and seriously aggravates spasmodic and slight organic strictures.

Symptoms.—In congestive stricture we not only find the common symptoms occasioned by an impediment to the free passage of the urine, but some swelling of the lips of the urethra, with reddening and eversion of them. There is also slight gleet exudation, and not unfrequently an abundant puriform discharge—in fact, urethritis of a marked kind, with a sense of weight or fulness in the perinæum, pain in micturition, and sometimes uneasiness in defæcation. This state of things constitutes a very troublesome affection, intimately connected with the various forms of urethritis, and exceedingly apt to relapse from apparently trivial circumstances, slight errors of diet, dyspeptic derangements, or any local sources of irritation.

The **Treatment** in these cases should consist in careful regulation of the diet and habits of life, and especially in the administration of citrate of

potash, and the saline aperient mineral waters, as those of Carlsbad and Friedrichshall. If there be much tenderness or weight about the perineum, the application of leeches, together with the use of the warm hip-bath, will be serviceable.

Congestive stricture, though more influenced by constitutional than local means in many cases, yet is often greatly relieved by the occasional introduction of bougies. In some instances a soft instrument, in others a steel one, will be found to answer best. Whatever is used, care should be taken to introduce it slowly and with every possible gentleness. With all care, some hæmorrhage usually follows the passage of the instrument; not from deep laceration, but simply as the result of compression of the mucous membrane; and the discharge of blood appears to be beneficial rather than otherwise.

ORGANIC STRICTURE.—This, the true form of stricture, is the result of the formation of dense fibroid tissue in the mucous membrane and submucous tissue of a portion of the urethra, in many cases extending to the neighbouring spongy tissue, or even further. This is produced as the result of chronic inflammation or of the healing of ulcers or wounds, and differs in no respect from the cicatricial fibroid tissue formed in other parts under similar circumstances. In its development it shows the tendency to contraction which forms the characteristic feature of all fibrous tissue produced as a consequence of inflammation, and thus leads to a narrowing of the canal it surrounds. The *causes of organic stricture* are: 1. Chronic inflammation of the mucous membrane, resulting from gonorrhœa. Repeated claps and long-continued gleet are by far the most fertile causes of this disease. The long continuance of the inflammation is more to be dreaded than its intensity in occasioning this mischief; hence it is of great importance not to allow gleet to run on indefinitely, as they will almost to a certainty be followed by constriction of some portion of the urethra. 2. The healing of an intra-urethral chancre always gives rise to a stricture. This is met with within an inch of the orifice, and is a comparatively rare form of the disease. 3. The most inveterate form of stricture arises from transverse laceration of the urethra from blows or kicks in the perinæum healing by a contracted scar. Several contusions of other parts of the canal may in the same way cause narrowing of its calibre. A more rare cause is the injury done to the urethra of a child by the lodgment of a calculus, or in the effort to extract it. 4. S. Gross states that it may be caused by habitual masturbation.

Age.—Stricture of the urethra may be met with at any age after puberty. The causes that usually give rise to it seldom come into operation, however, before the adult age; hence strictures are not very common before 25 years of age. Between that period and the age of 40 they most commonly originate, and may then continue for an indefinite period. The earliest age at which I have seen true organic stricture of the urethra has been in a boy 14 years old, when it had already existed for more than 12 months; it was situated one and a half inch from the meatus, and was so tight as only to admit of No. 1 catheter. It had given rise to a perinæal fistula, through which the greater part of the urine escaped. The boy could give no explanation of its occurrence, but it was probably traumatic. His attention was first directed to it by a sudden attack of retention. The stricture was hard and gristly, about half an inch long, and required urethrotomy for its relief. There was no calculus.

Seat.—The seat of organic stricture varies considerably; indeed, any

portion of the urethra may be affected by it, except the prostatic. It was at one time believed that the membranous portion of the canal was the most frequently affected by this disease. This, however, there can be little doubt, is an erroneous opinion. H. Smith examined 98 specimens of stricture contained in the different London museums: of these he found only 21 seated in the membranous portion of the urethra, whilst 77 were anterior to the triangular ligament; the majority of these being either in the bulbous portion, or a little in advance of this. Thompson, in his work on *Stricture*, states that, in an examination of 320 strictures, he found 215 at the junction of the spongy and membranous portions of the urethra; 51 in the spongy portion, from an inch in front of its commencement to within two inches and a half of the external meatus; and 54 at the external orifice, or within two inches and a half of it. The part most frequently affected is the first inch of the spongy portion; in the membranous portion, stricture is extremely rare, being almost invariably of traumatic origin when situated in this part. Thompson says: "I may confidently assert that there is not a single case of stricture in the prostatic portion of the urethra to be found in any one of the public museums of London, Edinburgh, or Paris." Occasionally strictures are multiple, two frequently occurring, and sometimes as many as four or five.

Pathological Appearances.—In describing the appearances commonly met with in a well-marked case of organic stricture, it will be most convenient to suppose that the whole canal has been laid open along its roof, and to consider the parts in the following order: 1. The part of the urethra anterior to the stricture. 2. The stricture. 3. The urethra behind the stricture. 4. The bladder. 5. The ureters and kidneys.

1. The **Urethra anterior to the Stricture** is perfectly healthy, unless it has been injured by instruments. If the cut edge of the mucous membrane be taken in a pair of forceps, it will be found to show a considerable degree of elasticity. Its colour is pink, and it is semi-transparent. The spaces of the spongy tissue beneath are empty and open, or filled with blood.

2. The **Stricture**.—At the narrowed part the surface of the mucous membrane is of an opaque white colour, marked by longitudinal ridges, and often parchment-like in appearance. If its edge be seized in the forceps it will be found to possess but little, if any, elasticity, and to be firmly fixed to the parts beneath. The submucous tissue, instead of forming a delicate areolar layer, is represented by tough rigid fibrous tissue firmly adherent on one side to the mucous membrane, and blending on the other with the cavernous tissue of the corpus spongiosum. The spaces of the spongy tissue are, in all more advanced specimens, obliterated for a greater or less extent near the stricture, so that the corpus spongiosum at this spot is converted into a dense solid mass. In very extreme cases the chronic inflammatory induration extends even to the areolar tissue beyond. The character of the stricture varies greatly. In some cases it is annular, encircling the whole canal equally for some little distance. When it is elongated, there is usually marked consolidation of the corpus spongiosum, as in Fig. 910. In other cases, again, annular strictures may be narrow and sharp-edged, and are then called "pack-thread" or "bridle" strictures; consisting of bands stretching across the urethra (Fig. 911). Sometimes there are several of these in close proximity to one another, leaving merely narrow passages between or under them. These bands occasionally stretch directly across the canal, but more commonly they take a somewhat oblique direction

(Fig. 911). It is not very clear how these bridles stretching across the urethra are formed. It can scarcely be by inflammatory exudation; it is more probable that they are occasioned by perforation of an annular narrowing of the mucous membrane by the point of an instrument. These various kinds of organic stricture are hard and elastic; sometimes, when old, almost cartilaginous in their density, feeling gristly and rough to the instrument that passes over them.

The *Amount of Constriction* varies greatly in organic stricture, from slight narrowing of the channel to almost complete obstruction of it. A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed upon the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures may

Fig. 910.—Stricture from Consolidation of Corpus Spongiosum.

Fig. 911.—Bridle-Stricture.

Fig. 912.—Stricture at the Anterior part of the Urethra.

occasionally, though very rarely, occur; the channel being so narrow, oblique, or tortuous, that the instrument cannot be passed through it. Stricture of this description, however, may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" is meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and even with such an aperture existing, I have never seen a case in which no urine whatever escaped by the meatus, unless, in consequence of injury or disease, a portion of the whole calibre of the urethra had sloughed away.

3. The **Urethra behind the Stricture** is dilated, often so as to form a considerable pouch, in which in rare cases phosphatic concretions may form. The mucous membrane is more opaque than natural, and its loss of elasticity is indicated by its being thrown into longitudinal folds; it is usually of an

ash-grey colour, indicating that it has suffered from chronic congestion or inflammation. The orifices of the lacunæ, and of the small glands opening upon it, are dilated, often to a considerable size. This is also very marked in the floor of the prostatic urethra. These small pits and hollows often cause considerable embarrassment in treatment, the instrument lodging in them after having safely passed the stricture. The cause of these changes is the extreme tension to which this part of the urethra is exposed during micturition, owing to the obstruction in front and the powerful hypertrophied bladder behind.

4. The **Bladder** in all well-marked cases of stricture shows evidence of chronic cystitis. Its mucous membrane is thickened, rigid, and of an ash-grey colour. If from any cause the condition has been aggravated before death, dark-red and purple patches will be found upon it. As a rule the cavity of the bladder is diminished, and its muscular coat greatly hypertrophied, giving rise to marked fasciculation of its inner surface. In exceptional cases, especially in old men, it may be dilated as well as thickened; sacculi are very common.

5. The **Ureters** are often more or less dilated. This is not, as was formerly supposed, due to regurgitation of urine, but to obstruction to the orifice of the ureter by the chronic inflammation of the mucous membrane, and the hypertrophy of the muscular coat of the bladder; the force that dilates the ureter being the force of secretion from the kidney. The further changes that occur in the pelvis and in the kidneys are fully described in Chapter LXV.

Symptoms.—The amount of **constitutional disturbance** set up by a stricture will vary greatly in different cases. In most instances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and duration of the stricture; but it is surprising how much constitutional irritation is set up in some systems by a stricture, even though it be not very tight. The interference with the free flow of urine ultimately causes secondary mischief in the kidneys, the nature and the symptoms of which have been described in Chapter LXV., to which I must refer the reader. In some cases the constitutional symptoms are rather of a nervous character; the patient suffering not only great pain in micturition, but being seized with rigors, followed by prostration, each time the urine flows over the tender and irritable surface.

The **Local Signs** of stricture are always well marked, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the free escape of the urine. The disease usually commences with the retention in the urethra of a few drops of urine after evacuation of the contents of the bladder; these escape and wet the clothes. The patient finds that he has to pass urine more frequently than usual, both by night and by day; there is some straining, perhaps a slight gleet discharge, and a feeling of weakness about the genital organs. The stream of urine becomes gradually smaller, as the part of the urethra anterior to the stricture is not distended as is normally the case during the act of micturition. Alterations in the shape of the stream, such as forking, twisting, and scattering, are often mentioned as symptoms of stricture, but are rarely observed; indeed, it seems hardly conceivable that a constriction in the bulbous portion of the urethra can determine the shape of the stream which flows from the meatus. As the disease advances, these signs

necessarily become more marked, until they may terminate in complete retention ; they often come on in a very insidious manner, however, and when the patient seeks advice he is found to be already the subject of a very tight and intractable stricture ; indeed, in some cases, the first circumstance that directs the attention of the patient to his complaint is the sudden occurrence of retention of urine.

Examination of the Patient for Stricture.—In all cases of suspected stricture, the Surgeon should, if possible, see the patient pass water before using an instrument. He will thus be able to judge of the actual amount of obstruction. It sometimes happens that the canal, though not greatly narrowed, is tortuous and indurated, so that an instrument enters with great difficulty, although the patient passes a fair stream of urine. Such a case might readily be mistaken for a very tight stricture if the examination were commenced by attempting to pass an instrument. The existence of a stricture can however be determined with certainty only by the introduction of an instrument. In exploring the canal in a suspected case, two points have to be ascertained—the existence of a stricture, and its degree of tightness.

The *Existence of a Stricture* is best determined by passing a soft conical French bougie about No. 8 (English scale). It must be slightly warmed and well oiled. This will pass readily, unless the canal be distinctly constricted, when it will be arrested at the narrow point. In this exploration, too small an instrument must not be used, lest it hitch in the fossæ of the urethra or against the verumontanum, and this accidental arrest be mistaken for the obstruction produced by a stricture ; or it may pass through the stricture, and thus mislead the Surgeon. The existence of a stricture having been ascertained, the next point is to determine its *degree of tightness*. This is best done by withdrawing the instrument previously used, and then introducing a smaller one about the size of the stream of urine that the patient passes. If this fail to enter the stricture, a still smaller one must be used, until that size is reached which can

be introduced with but a moderate degree of force. In this way the existence, the seat, and degree of tightness of the stricture, are ascertained.

A soft instrument should always be used by preference for this preliminary examination, as it causes less pain, and with the most ordinary skill and care it is impossible to do the patient any injury with it. There is no doubt that information as to the length, degree of induration, and form of the narrowing, may be gained by the experienced Surgeon by means of a metal bougie ; but the knowledge thus gained is not sufficient to counterbalance the greater ease and safety of a soft instrument.

The slighter narrowings of the urethra are not easily recognized by the means just described. For this purpose the conical or olive-headed bougie (Figs. 913 and 914) will be found most useful. The conical shape of this instrument enables it to pass readily towards the bladder, but on withdrawing it the

shoulder hitches on any narrow part. The instrument should be graduated in inches, so that the exact distance of the stricture from the orifice can be readily determined. If it be desired to determine more accurately the seat of the stricture, the distance of the orifice of the bladder from the meatus externus must first be determined by carefully passing a graduated "catheter à boule," and noting the exact moment at which the urine commences to flow. The graduated olive-headed sound is then introduced for the same distance, and slowly withdrawn. If the hitch be felt between one inch and one and three-quarters, the stricture is in the membranous part; if between one and three-quarters and three inches, it is in the bulbous portion. For the purpose of measuring slight strictures, Otis, of New York, invented an instrument which he calls the "urethrometer" (Fig. 915). It consists of a straight tube, the end of which can be dilated into a sort of fenestrated sphere, and the size to which it is dilated is registered on a small dial on the handle. The instrument can be readily introduced into the bladder, if necessary, but there is no advantage in so doing. When in the urethra, behind the stricture, the bulb is gradually expanded till it is just held, but not tightly grasped. It is then drawn steadily forward, and when it is stopped the bulb is gradually diminished till it passes the stricture. The exact size of each part is thus registered on the dial.

The **Treatment** of organic stricture of the urethra may be conducted by

Fig. 915.—Otis's Urethrometer. A, Open; B, End closed.

the following methods:—1, Gradual Mechanical Dilatation; 2, Continuous Dilatation; 3, Electrolysis; 4, Forcible Expansion or Rupture; 5, Internal Urethrotomy; 6, External Urethrotomy or Perineal Section; 7, Excision. Whatever plan of treatment be adopted, the Surgeon must bear in mind that his operations have to be conducted upon a tender canal endowed with exquisite sensibility, in which improper violence may set up a degree of irritation that will readily extend to neighbouring structures, and thus endanger the life of the patient. But, though it is necessary to recollect this, he must not run into the opposite and equally dangerous extreme of adopting inefficient measures for the removal of the obstruction. A bad stricture is one of the most serious diseases to which the human frame is liable, and will almost inevitably, if left to itself, terminate fatally by the induction of renal disease, or of serious local complications. We must therefore not hesitate to adopt sufficiently energetic measures for its removal; and if these be properly conducted, there is scarcely any affection in which the Surgeon can afford his patient greater relief. At the same time, however, that local means are being used, constitutional treatment should not be neglected. Organic stricture is often more or less associated with a spasmodic or congestive condition of the urethra, and requires the same constitutional treatment, modified according to circumstances, that is necessary in these affections—proper regulation of diet, avoidance of all articles of food that generate

urates, and care not to allow the urine to become too concentrated. Attention to the maintenance of the healthy action of the liver and skin will also tend much to increase the patient's comfort, and to ward off the more serious consequences of stricture.

In all except the slightest cases of stricture it is advisable, before beginning mechanical treatment, to subject the patient to constitutional remedies to diminish as far as possible the congestion and spasm which may be present. If any serious difficulty be anticipated, and if the circumstances of the patient permit it, he should be confined to bed for a day or more. The bowels should be freely opened, and he should sit for some time in a hot hip-bath, morning and evening. A morphia suppository may be administered at night, and if the signs of congestion be well marked, a few leeches may be applied to the perinæum. Occasionally blisters over the seat of stricture, when it can be felt clearly from without, may be of service. By these means alone, a stricture which at first seemed almost impermeable may be so far relieved as to take a No. 4 or 5 catheter.

1. **Gradual Mechanical Dilatation**, as it is erroneously termed, is the usual and certainly the most successful mode of treating ordinary strictures:

Fig. 916.—Conical Bulbous Bougie.

but it is not the mere stretching or forcible dilatation of the stricture that cures it. The means employed to produce dilatation tend to promote the absorption of chronic inflammatory products in and underneath the mucous membrane, which especially constitute the stricture.

The instruments that are used for dilatation are either metallic, such as

Fig. 917.—Conical Bulbous Catheter.

silver catheters, steel sounds, or plated bougies; or made of some soft and yielding material, as gum-elastic catheters, and catgut, whalebone, or elastic bougies. Though each Surgeon will mostly prefer one kind of instrument to another, it is well not to be too exclusive in the use of any one; for it will be found that in particular cases it is advantageous to depart from the ordinary practice, and that the Surgeon may modify with great benefit to his patient the mechanical means that he adopts. As a general rule, if the stricture can be treated from the first by soft instruments, so much the better. They cause less pain and irritation, and the danger of making false passages is avoided. When the stricture is tight, cartilaginous and of old standing, it is, however, frequently impossible to pass any soft instrument through it, and then a well-made steel bougie or a silver catheter must be used. When once dilatation has been carried to a certain point, for instance to the introduction of a No. 5 catheter, then soft instruments can always be employed if preferred; but at this stage of the treatment, when the risk of making a false

passage is very small, conical steel bougies will in many cases be found not only more efficient but quite as comfortable to the patient.

The best soft instruments are the conical bougies and catheters with *bulbous ends* (Figs. 916 and 917). Their introduction excites far less irritation and pain, with much less likelihood of bleeding than that of metallic instruments. In most cases of ordinary stricture they will be found to be the safest and most agreeable instruments to use. They will often glide through a tight irritable stricture, when all other instruments, especially metallic ones, fail to pass.

A *filiform bougie* made of whalebone, gum-elastic or catgut, may sometimes be passed through a very narrow stricture, when every other instrument fails to do so. The ordinary English gum-elastic catheter is of little use in the treatment of stricture by simple dilatation. A conical instrument, the point of which is small enough to pass readily through the stricture, can easily be pushed on so as to exert considerable dilating force with its thickest part. An ordinary English gum-elastic catheter which is the same size throughout cannot be got into the stricture at all so as to exert any dilating force, as it is not stiff enough to be forced into it. If a stylet be used to stiffen it, it becomes as capable of making a false passage as a steel bougie, and is not under the same control.

If the stricture be not only very tight, but twisted, the plan recommended by Brodie may advantageously be employed. This consists in taking a fine catgut bougie, and bending it, as represented in Fig. 918, about an inch from the point, so as to follow the track of the stricture. In this way, strictures that are otherwise impassable may be rendered pervious with comparative ease.

If metal instruments are used the most efficient are Lister's *conical steel bougies* (Fig. 919). There should be a difference of three sizes between the thinnest and the thickest parts of the straight portion of the instrument by which the dilatation is performed. The point should be well rounded,

Fig. 918. —
Catgut Bougie
bent to shape of
Stricture.

Fig. 919. — Lister's Conical Steel Bougie.

and the instrument passes more readily if there is a slight constriction immediately beyond it. The instrument should be made of nickel-plated steel and be highly polished. It should have a broad metallic handle, which transmits any sensation communicated to the point more readily than a wooden one. That this instrument will pass much more easily than a catheter is self-evident, and the latter should be used only when it is intended to tie it in. If a catheter be used it should be made very solid and stiff. The rings should be large, so as to serve for a handle, and the eyes well rounded off and somewhat depressed, so that they may not scrape the urethra. These

struments should be used with every possible care and gentleness, but it is useless to think of passing a catheter through a tight stricture without the employment of some degree of force. The catheter will not "find its own way" here as it does in a healthy urethra, but it must be guided by the hand of the Surgeon; and there is scarcely an operation in surgery that requires more delicacy of manipulation than that of passing an instrument through a tight stricture. Some force must be used, but the skill is shown in proportioning this to the amount of resistance, and in using it in a proper direction. The appearance of force is indeed often greater than the reality; for, though the point of the catheter have passed a tight stricture, it may still require considerable pressure to push the rest of the instrument through it. With a conical steel bougie less force is required than with the catheter, as the stretching is not done with the point, which should pass easily through the stricture, but with the expanded part beyond, which from its conical form passes without much difficulty.

Introduction.—Catheters and sounds are best introduced by laying the patient flat upon his back, with the pelvis somewhat raised, and the head and shoulders low. The Surgeon, standing on the left side, inserts the instrument, well warmed and oiled with "Lund's oil" (p. 1116) or vaseline, into the urethra with its concavity turned towards the left groin, and passes it down the canal, at the same time drawing the penis upwards with his left hand, so as to put the mucous membrane on the stretch. As the instrument approaches the triangular ligament, the handle is carried to the mesial line, and at the same time raised perpendicularly; and, as its point passes under the pubes, it should be kept well against the upper surface of the urethra, and made to enter the bladder by depressing the handle towards and between the thighs. The surest guide to the bladder is the upper surface of the urethra, which is more fixed than the lower, and less liable to the existence of fistulous openings or false passages. Should difficulty be experienced, the introduction may be facilitated by injecting and slightly distending the urethra with olive oil before passing the instrument. If the meatus is small this must be enlarged by a short incision downwards.

If difficulty is found in introducing the instrument, and if any doubt exist as to its being in the right passage, the finger must be introduced into the rectum and its position felt for. If the point of the instrument has left the urethra this may be recognized by its being too thinly covered and too near the gut, or by its being out of the middle line.

Chloroform or ether need be administered only if the stricture be very tight or the patient irritable. Under the influence of an anæsthetic, however, many strictures may readily be passed with metallic instruments that are not pervious in any other way.

Results of Introduction of an Instrument.—The introduction of an instrument usually gives rise to a smarting, painful sensation in the urethra: this is generally most severe as the point approaches the neck of the bladder, and is then sometimes attended with nausea and sudden faintness. As a general rule, the instrument should be passed every second or third day, and when introduced should be left in for about five minutes, or until the spasm of the urethra induced by its introduction has subsided. If, however, the stricture be extremely tight, a very small catheter only having been introduced, the instrument may be left in for twenty-four or forty-eight hours,

When it will be found that, however tightly grasped it had been originally, it has become loosened; a slight discharge being at the same time set up from the urethra. It may then be readily withdrawn, and, when the irritation has subsided at the end of a couple of days, a considerably larger one may be introduced.

The augmentation of the size of the instrument should be very gradual. It is fully sufficient to increase it by one number at each time of introduction. Many urethrae will not bear even this, and it becomes necessary to pass the same instrument on two or three successive occasions before a larger size can be introduced. The size may be gradually increased until the largest is reached which the urethral orifice readily admits; but as soon as No. 14 or 16 can be introduced with ease, it should not be passed so frequently as before; it may be passed every seven or ten days, and gradually with less frequency. But a patient who has once suffered from a tight stricture should pass an instrument at least once a month for the rest of his life.

If the size of the instrument be increased too rapidly, irritation may be set up, and inflammation of the testicles, and abscess in the perinæum or prostate, induced. I have more than once had occasion to regret being in too great haste to increase the size of the instrument; and by augmenting it by two or three numbers at one sitting, I have seen the patient thrown back for weeks by the supervention of some of the affections just mentioned.

By gradual dilatation, properly carried out, most strictures may be considerably relieved in the course of a few weeks; and the majority may be brought to the full size by continuing the treatment for a sufficient length of time. Some, however, cannot be cured in this way; it would appear that the tissue of which they are composed is so rigid that, although they may be expanded up to a certain size—say up to No. 5 or 6—it is impossible to go beyond this. In other cases there is a great tendency to relapse, and to a return of the constriction; the stricture rapidly becoming tighter as soon as the introduction of the instruments is discontinued, even though it be dilated to the full size of the urethra, up to No. 16, for instance. In some instances the relapse is almost instantaneous, micturition being as difficult as before immediately the catheter is withdrawn. In these cases recourse must be had to other measures, which will be described.

Accidents attending Catheterism.—The introduction of instruments occasionally gives rise to certain troublesome and even dangerous sequences. Amongst these, syncope and rigors, hæmorrhage, and inflammatory irritation about the urethra or testes, are the most common.

Nervous Symptoms, Rigors, and Urethral Fever.—The subject of urethral fever following the use of instruments on the urinary organs in persons affected with chronic or subacute interstitial nephritis has already been discussed at p. 1003. There is no condition in which this untoward complication is more apt to occur than in the treatment of stricture of the urethra, owing no doubt in a great degree to the frequent occurrence of chronic and possibly unsuspected kidney disease in old-standing cases.

Various degrees of constitutional disturbance may be produced by the passage of an instrument through a stricture. In nervous and sensitive individuals this operation is often attended with a sensation of faintness and chilliness as the instrument enters the bulb or membranous portion of the urethra. This sensation is not due either to pain or to fear. It is purely reflex, and

in most cases soon passes off, being less likely to recur as the urethra gets more accustomed to the use of instruments.

If a person liable to these nervous feelings is exposed to a chill, a severe rigor may come on some hours after the passage of the instrument, or the same thing may happen when there has been no predisposition to it, the rigor coming on suddenly and without warning. This is more apt to occur when the stricture is tight; when metallic instruments have been used—possibly with some degree of force, and, though during a considerable length of time—perhaps in vain attempts to penetrate the stricture. The rigors in these circumstances are very severe, so much so as to resemble an attack of ague. During the rigor the temperature rises considerably, often to 104° or 105° . The subsidence of the rigor is marked by profuse sweating, and is usually attended with great exhaustion. This occurrence is always very alarming, and, though usually not attended with positive danger, leaves the patient weak and exhausted; and if he be old, of broken constitution, or the subject of chronic kidney disease, a fatal result may rapidly ensue. In these distressing cases death may occur at different periods and in different ways. The earliest period at which I have seen a fatal termination has been in nine hours: usually it takes place in from 24 to 48 hours after the first rigor. The immediate cause of death may be coma, exhaustion, or cardiac syncope.

The cause of these rigors is exceedingly obscure. Constitutional nervousness or timidity has certainly nothing to do with them. They occur in the strongest and most courageous men, and they very rarely follow the use of the catheter in women. I have only once seen these effects in the female, in the person of a young married lady, strong and healthy, who had a stricture of the orifice of the urethra, which I dilated by a two-bladed dilator. Twenty hours after the operation, she had three most intense rigors followed by profuse sweatings. In men they may occur after dilatation of any part of the urethra, but they are much more frequent when the stricture is seated in the bulb or in the membranous portion of the canal. I have heard of one case, however, in which a fatal rigor followed incision and dilatation of the meatus. I doubt whether severe rigors occur unless there have been some traumatic lesion, such as abrasion or rupture of the mucous membrane of the urethra. Rigors certainly follow the use of metallic instruments more frequently than that of the softer kinds, which are less likely to produce such mischief. Rigors are not prevented by the use of anæsthetics. Some of the worst cases that I have seen have occurred after prolonged instrumentation under anæsthetics.

Treatment.—The rigor is best prevented by gentleness in the use of instruments; by the employment of soft, rather than metallic ones; by guarding most carefully against a chill, the patient being kept in a warm room during the whole of the day; and by the administration of a full dose of opium and quinine before the use of the instrument.

When a rigor has set in, the patient should be wrapped up in blankets; a glass of hot spirits and water or tea may be given, to be followed up by quinine and opium. The sweating, which is often so profuse as to wet through pillow and bed-clothes, must be encouraged. When it has ceased, the patient should be rubbed dry and wrapped in dry warm blankets.

Suppression of Urine is a rare accident after simple dilatation, being more common after the more severe methods of treatment, such as forcible

dilatation. The symptoms are at first those just described, the patient suffering from a rigor, with rapid elevation of temperature, dry skin, and vomiting. The secretion of urine entirely ceases, or at most a few drops darkly stained with blood escape. The patient usually dies in from two to three days, unless the secretion returns. In these cases the kidneys are usually found more or less extensively affected with chronic interstitial inflammation; but cases have been recorded in which the microscope revealed but little change. They are usually gorged with blood. The condition would seem to arise from reflex nervous disturbance of the kidney, but the pathology of the process is very obscure. The *Treatment* consists in dry cupping over the loins and hot-air baths. Large warm water enemata, with a view of "fomenting the kidneys," have been suggested. The bowels must be freely opened by the compound jalap powder. Possibly in some cases pilocarpine hypodermically in doses of from $\frac{1}{10}$ to $\frac{1}{4}$ of a grain might be of use.

Hæmorrhage, which is sometimes rather profuse, may follow the introduction of a catheter, especially if the stricture be congestive, and the instrument employed small. It generally ceases of itself; but, if it be troublesome, the application of cold will check it.

The **Inflammation** about the urethra and in the testes that occasionally occurs during the treatment of stricture, is best guarded against by not using too large catheters, and by directing the patient to abstain from much exercise during the time of their introduction.

False Passages are occasioned by the instrument passing out of the urethra through its coats into the surrounding tissues. They are especially apt to occur in tight bridle-strictures, when a small instrument is being used, more especially if the direction of the constriction be somewhat oblique, so that the point of the sound is thrown against the side of the canal (Fig. 911). The extent and situation of a false passage necessarily vary according to the position of the stricture; and the danger is usually in proportion to its depth. The false passage usually takes a direction downwards and to one side of the urethra. If the stricture be far forward, it may run in the corpus spongiosum; but if it be in the usual situation, it may perforate the lateral lobe of the prostate, or run between this and the rectum, being unable to extend upwards on account of the rigid nature of the structures in this situation. When the false passage merely perforates the corpus spongiosum, running parallel to the urethra, and opening again into the canal, or when, perforating a portion of the prostate, it enters the bladder, it is not necessarily attended with much danger; but when it enters the areolar tissue between the bladder and the rectum, admitting urine into the recto-vesical space and about the neck of the bladder, then the most serious consequences, such as inflammation and abscess, are apt to ensue, and may prove fatal.

At the moment when a false passage is made during the introduction of an instrument, by the Surgeon using too much force or pressing in the wrong direction, he feels the point make a sudden slip, which the plane of the handle shews to be to one side of the urethra. The patient complains of severe pain, and is often conscious of a laceration; there is a grating or rough sensation communicated by the tissues against which the instrument has passed; and though it have entered deeply, it will be found not to have reached the bladder. On the Surgeon introducing his finger into the rectum, he probably feels the point of the instrument in the areolar tissue between the gut and the bladder

on withdrawing it, it will be found covered with blood, and there will be free hæmorrhage from the urethra.

The Surgeon knows when he has entered an old false passage by the charge that takes place in the direction of the instrument, by its not reaching the bladder and by the rough sensation communicated to it, very different from that afforded by the smooth lining of the urethra. The patient is often conscious of the existence and of the entry of the instrument into the false passage, and will warn the Surgeon of it.

If the Surgeon be aware that he has made a false passage, he should, if possible, at the time of the accident pass a catheter into the bladder, and leave it there for a few days until the laceration has healed. If there be an old false passage he must be careful, by keeping the point of the instrument away from it, not to enter it, lest during the introduction of the catheter he raise with the point of the instrument the valvular angle that intervenes between it and the urethra; every time that this is opened up tends to lessen the chance of closure of the aperture, whilst, overlapping the urethra it interferes with the onward passage of the instrument into the bladder. By withdrawing the instrument and changing its direction, the false passage may often be avoided, and the bladder reached. Should there have been much difficulty in introducing the catheter, the better plan will be to allow it to remain in for two or three days, when the false canal may possibly close.

It has already been stated that, in certain forms of stricture, gradual dilatation does not succeed in effecting a permanent cure. In these cases, five plans of treatment have been recommended: continuous dilatation, electrolysis, forcible dilatation, division by the knife, and excision. These methods will now be described.

2. Continuous Dilatation is merely a modification of the preceding mode of treatment, and is useful only in very tight strictures. A small instrument is passed and tied in. In tying the catheter in, care should be taken that it does not lie too far in the bladder. It should be pushed backwards and forwards until the exact point is found at which the eye is inside sufficiently to allow the water to flow, and be fixed at this point. It is best retained by soft thick silk tied round the corona of the glans, or fixed to the body of the penis by a piece of plaster, care of course being taken not to produce strangulation. In from twelve to twenty-four hours, although it may at first have been tightly grasped, the catheter will be found to be quite loose, and urine will escape beside it. It must now be changed for a larger one. In doing this, the fresh instrument should be ready, so that the moment one is removed the other may be introduced. A neglect of this precaution, especially when false passages are present, may seriously increase the difficulty of passing the fresh catheter. By the second day a slight-discharge will be found to have been set up from the urethra. The treatment should be continued till the urethra reaches the size of No. 5 or 6, which it will do in a few days at most, after which it is not necessary. The catheter may be closed with a small wooden plug, so that the patient can draw off his own urine, or, better still, an india-rubber tube may be attached so as to drain the bladder. In cases in which a gum-elastic catheter cannot be passed, a small silver one may be tied in, and replaced by a gum-elastic at the first change. When nothing but a filiform whalebone or catgut bougie has been passed, it may still be tied in, as the urine will usually find its way beside it even when it seems at first to be

tightly grasped ; and in twelve hours or a little longer it may, in most cases, be changed for a fine gum-elastic catheter. This plan of treatment is of great use in cases in which considerable difficulty is found in introducing the instrument, but it has the disadvantage of being extremely apt to set up cystitis. If the treatment be continued beyond three days, the urine will almost always be found to be alkaline ; and this is scarcely to be wondered at when we consider the way in which the bladder is, as it were, opened up to the air. The risk of cystitis is much diminished by draining the bladder, for then no urine is left to decompose, and the mere contact of the soft instrument with the walls of the bladder seems to cause but little irritation by itself. In rare cases, sloughing of the urethra may take place at the seat of stricture, leading to perinæal abscess. A case of this kind occurred some years ago in University College Hospital.

3. Electrolysis.—The cure of a stricture by destroying the fibroid tissue which narrows the urethra, by electrolysis, was introduced by Mallez and Tripier, more than twenty years ago, but did not find much favour. Its results were uncertain, and in some cases it was followed by perinæal abscess and other complications. It has been revived by Newman of New York, Fort of Paris, and has been practised in this country by Bruce Clarke, Edwards and others. The operation consists in passing the negative electrode, which is like an ordinary soft catheter with a metal tip, down to the stricture, and placing the positive, which must have a large moist pad, on some part of the body, as the back. The strength of the current is accurately measured with a galvanometer and should be from $2\frac{1}{2}$ to 5 milliampères. The electrode is held gently against the stricture, and after a period varying from a few minutes to half an hour, it will be found to have passed through. The operation should give little or no pain. It requires to be repeated two or three times, a larger electrode being used on each occasion. Fort of Paris, who demonstrated his method in this country in 1889, employs a linear electrolyser resembling a Maisonneuve's urethrotome. It consists of a long bougie 2 millimeters in diameter, terminated by a filiform guide. The current is conveyed by a fine wire in the bougie to a blunt triangular blade of platinum which projects from the instrument and rests against the stricture.

Newman, who strongly advocates this treatment, asserts that he has operated on two hundred cases without an accident and without a relapse. It is asserted that the current used in this way does not actually cauterise, but causes chemical decomposition and absorption of the scar tissue. This method of treatment is again on its trial. That it is not more dangerous than other modes of treatment and that by it the canal may be restored to its normal size, seems to be tolerably clearly proved, but better evidence is wanted than has as yet been furnished that it effects a permanent cure without any tendency to a relapse. If it can do this, it stands alone amongst all methods of treating stricture.

4. Forcible Expansion or Rupture.—Forcible and rapid dilatation causing the expansion and rupture of the stricture, is a method that, originally practised by Luxmoor, Arnott, and Buchanan of Glasgow, has been revived, and ingeniously modified in detail, by many Surgeons, amongst whom Reybard, Maisonneuve, Perrière, Wakley, Holt, Thompson, and Hill are the most conspicuous. However varied the means by which strictures are thus

treated, the instruments employed may be arranged in three groups : *a.* Those that act as sliding tubes ; *b.* Those that expand by a screw mechanism ; and *c.* Those that act on the principle of a wedge. It may also be effected by the passage of the conical steel bougies already described, one after another, while the patient is under an anæsthetic, though this method is perhaps more properly included under simple dilatation.

a. Sliding Tubes were first employed in the treatment of stricture by Desault at the close of the last century, subsequently by various French Surgeons, and in later years by Hutton of Dublin, and very extensively and successfully by Wakley. The mode of application of these tubes is as follows. A long conductor is introduced through the stricture into the bladder, and over this a catheter, either of gum-elastic or silver, is passed, which in its turn is made to serve as a conductor to a larger one. In Wakley's instrument the conductor, or "urethral guide," consists of a small silver catheter, which, after being passed through the stricture, has a long steel rod screwed into it. Over this a silver tube is passed, which in its turn is made to serve as a conductor ; and thus the stricture may be rapidly dilated by passing one tube over another until a full size is reached. The only difficulty in this very ingenious method—which is, however, common to it and every other plan of treating stricture by dilatation—consists in the first introduction of the "urethral guide ;" when that has once passed through the stricture, the tubes

Fig. 920.—Thompson's Stricture-Expander.

must follow as a matter of necessity. They cannot possibly go wrong ; and, as no laceration of the stricture is effected by the instrument, it appears to be a safe means of employing rapid dilatation.

b. The method of forcibly expanding a stricture by the introduction into it of a small two- or four-bladed instrument, fashioned somewhat like a narrow beaked sound, and which, by **Screw-Mechanism** in the handle, admits of being opened out so as to stretch the stricture to an extent corresponding to the distance at which the blades are screwed apart, has many advocates ; and various ingenious contrivances have been invented to effect this object. More than half a century ago, Luxmoor attempted it by the use of a four-bladed instrument. Some years later Civiale invented a stricture-expander ; and subsequently two-bladed instruments, having this end in view, were introduced into practice by Perrève, Lyon, and Thompson. The accompanying drawing (Fig. 920) is a representation of the instrument used by the last-named Surgeon ; it answers the intended purpose admirably, the expansion of the blades being effected by a screw worked by turning the handle. This should be done very slowly, several seconds being allowed to elapse between each turn of the handle, so that the tissue composing the stricture may be gradually stretched, and the canal of the urethra at the seat of stricture dilated beyond the full size, so as to be over-stretched ; the extent of dilatation may be carried up to 16 or 18, and is marked on a scale attached to the handle of the instrument. If this

operation be done slowly, little if any bleeding results, and there is no evidence of deep laceration of the wall of the urethra at the strictured spot. A large gum-elastic catheter may then be passed, and the urine drawn off. It is not usually necessary to leave the catheter in the bladder, though there can be no objection to doing this for forty-eight hours, after which the patient may have one passed occasionally in order to maintain the dilatation.

c. The rupture or splitting of the stricture by an instrument acting on the principle of a **Wedge**, was recommended by Reybard, and very extensively employed by Holt. The instrument used by him is represented in the accompanying figure (Fig. 921). It consists of two grooved metallic blades joined at the extremity. Between these a tube is slipped along a wire, which in its descent separates the blades at a considerable angle, and thus splits up the stricture. In this way the contracted part of the urethra is at once enlarged to its normal diameter, so as to admit a full-sized catheter, by which the urine is then drawn off. The introduction of the catheter should be had recourse to at first on alternate days, and afterwards at longer intervals. Holt believes that the effects of the dilatation are entirely confined to the morbid contraction, the healthy portion of the urethra not being injuriously disturbed by the expansion of the instrument.

Berkeley Hill invented a modification of the dilators previously in use

Fig. 921.—Holt's Instrument for Splitting Strictures.

which presents several advantages. He thus describes it: "The instrument consists of a split sound, which equals in calibre a No. 2 or 3 catheter. The halves of the split sound can be separated by passing between them a wedge fixed on a slender stem. The wedge is prevented, by two dovetail grooves at its hinder part, from leaving the sound which acts as a guide during the passage of the wedge down the urethra." "The advantages claimed for this instrument are: simplicity of construction; the central guide of Holt's instrument is not needed, hence the split sound can be passed through narrower strictures. Next and chiefly, diminution of resistance, and consequently the more immediate application of the rupturing force—the wedge—to the impediment to be overcome. The force needed to push Holt's dilator is sometimes very great, and the attempt has been abandoned, or the instrument has broken, even in skilful hands, from this cause. Much of the force is expended on the continuous friction outside the tube along the split sound, and inside along the guide. In the wedge-dilator the friction-surface is reduced to two dovetail grooves, which together do not exceed half an inch. For this, the force required is so small that one hand suffices to overcome the resistance." The instrument can, if required, be adapted to a conducting sound, such as is described afterwards under Internal Urethrotomy.

Another instrument of the same class has been devised by Bigelow (Fig. 922). It consists of a filiform conducting sound, which is first passed. The guiding rod is then screwed into this and passed into the bladder, pushing the conducting sound before it. The cup-shaped cap at the upper end of the guide rests on the glans, while the Surgeon's left hand grasps the body of the penis.

The stricture is then dilated by forcing down the olive-shaped divulsor, which is deeply grooved to run on the guiding rod. Being olive-shaped it passes more easily, as in Hill's dilator, not being grasped by the whole canal.

Forcible dilatation is doubtless a most efficient mode of treating stricture: by it the urethra is immediately restored to its full diameter, and the result which it may take weeks to accomplish by simple dilatation is at once obtained. It is, however, by no means devoid of danger. The urethra is not dilated, it is split, and a longitudinal rent in the mucous membrane is made corresponding to the length of the stricture. The shock produced by so violent a proceeding is often severe, and suppression of urine has followed in several recorded cases. It has also sometimes been followed by urinary abscess, and more rarely by pyæmia. What it gains in rapidity it loses in safety, and

Fig. 922.—Bigelow's Divulsor.

to adopt it as a universal mode of treating strictures would lead to the loss of many lives that might have been saved by more gentle treatment.

5. Division of the Stricture may be practised either from *within* the urethra, or from *without*, through the perinæum.

Internal Urethrotomy.—The division *from within* may be performed in two ways: either by cutting through the stricture from before backwards, or by passing an instrument through it, and dividing it from behind forwards. The first method is attended with great danger unless the instrument is provided with a guide which ensures that the urethrotome is really in the stricture. On the other hand, the operation of cutting from behind forwards could not, until recently, be performed unless the stricture was capable of admitting a No. 5 at least. The Surgeons to whom we are most indebted for improvements in the instruments employed, are Van Buren, Gouley, and Otis of New York, Maisonneuve of Paris, and Berkeley Hill of London. The objects in view have been, first, to provide a safe and certain guide for a small cutting instrument, and secondly, so far to diminish the size of the instruments as to make them available for strictures not capable of taking more than a No. 1 catheter. Lastly, as it was found that the great mobility of the urethra rendered it difficult in many cases to divide the stricture, a combination of stretching and cutting was introduced by Otis, which greatly facilitates the operation.

The guide to the bladder may be obtained in two ways. A fine whalebone bongie having been passed through the stricture, the urethrotome may be so constructed, by being tunnelled for a short distance at its point, as to slide over this into the bladder. But a better plan is the employment of *Maisonneuve's sonde conductrice*, or conducting sound. This is a very fine gum-elastic bongie, provided with a male screw at the end (Fig. 923 c). This is first passed on till it is judged to be in the bladder. A small catheter corresponding to a No. 1, having a female screw at its extremity, is then screwed on to it and passed onwards, while the conducting sound coils up in the bladder. If the urine flow, it is then certain that the conducting sound has passed in the proper direction. It is now withdrawn again, the conducting sound being left in position. The catheter is now replaced by the urethrotome, which screws in the same way. Berkeley Hill invented a very ingenious urethrotome for cutting from behind forwards, in which a very fine knife can be protruded from an instrument not larger than a No. 2. Another instrument invented by the same Surgeon for cutting from before backwards is represented in Fig. 923. It combines the principles of several others, and has been found to work most successfully. It is thus employed. The conducting sound having been passed and ascertained to be in the bladder, the female screw *b* is applied to the male screw *a*, and the instrument passed through the stricture. The blades *i* and *h*, when closed about equal a No. 3 catheter in size. The point *b* is about equal to a No. 1. The instrument having been passed, the wedge *e*, which contains a knife *d* concealed in a shield *c*, is now inserted between the blades and passed steadily down. The blades thus separated stretch and steady the urethra; and when the stricture is reached, the shield *c* stops against it and prevents further progress. The small concealed knife *d* is then protruded by pressing the button at the top of the instrument, and as soon as the finger is removed it is withdrawn again by the spring *l*. The wedge can then be passed on a little further, and if it hitch again the knife can be again protruded. By this means the urethra is cut only at

Fig. 923. Berkeley Hill's Dilator and Urethrotome. *A*, Front View; *B*, Side View; *c*, Conducting Sound with small male screw at *a*; *b*, female screw; *c*, sheath for concealed knife; *d*, knife protruded; *e*, wedge for separating the blades *A* and *i*, the knife is on the posterior aspect of the wedge; *f*, rod for carrying the wedge; *g*, rod for protruding the knife; *h*, screw for regulating the distance to which the knife can be protruded; *i*, spring, to draw back the knife and keep it concealed, except when protruded by pressing the button opposite *A* and *B*. (In Fig. *B*, the button should have been represented as depressed.)

the points of stricture, and no more wound is made than is absolutely necessary. The incision is always made downwards towards the floor of the urethra. This instrument may be employed in almost any stricture that will admit the conducting sound.

Maisonneuve's urethrotome consists of a fine steel sound, deeply grooved along its upper surface. If necessary, it is guided into the bladder with a *sonde conductrice*. The stricture is divided by means of a triangular blade with a blunt apex and cutting anterior edge, which is passed along the groove in the sound. Teevan modified this instrument by using a guarded knife similar to that of Hill's urethrotome.

After the operation of internal urethrotomy, a full-sized instrument should immediately be passed, but it is not usually necessary to tie it in. Hill recommended that the patient should pass his water in a hot bath during the first day or two after the operation, and that no instrument should, unless required, be introduced for ten days. A full-sized bougie is then passed daily for a few days, and after that every second or third day for three or four weeks. After that, the patient should be taught to pass it for himself, and continue to do so at least once a month for the rest of his life.

The operation of internal urethrotomy is, of course, required only in exceptional cases. These are chiefly resilient or very irritable, and some very tough strictures. In resilient strictures, dilatation fails because the stricture, though admitting of expansion, immediately relapses. In very irritable strictures, the patient cannot bear the pain of dilatation. In some very tough strictures, simple dilatation fails, and then internal urethrotomy or forcible dilatation is required. In all these cases, the division of the stricture from within removes at once all difficulty in treatment; and I have frequently employed this very simple method with the most marked and permanent success. In fact, in strictures of the scrotal or penile portions of the urethra, one or other of the above conditions — resiliency or irritability — commonly prevails, and I have generally found internal urethrotomy the best mode of treatment.

Result.—The risk attending the operation is not great, and diminishes as the stricture approaches the orifice of the urethra. It is not, however, free from danger. The accidents that may happen are, perinæal abscess, extravasation of urine, hæmorrhage, and orchitis; and in some rare cases it may be followed by pyæmia. If the kidneys be diseased, it may, like any other operation for stricture, give rise to fatal acute interstitial nephritis. Perinæal abscess usually results from cutting too deeply, so that the knife completely divides the corpus spongiosum. Such abscesses most frequently form beneath the accelerator urinæ, and burrow forwards, directed by the expansion of that muscle to the root of the penis. They contain a mixture of urine and pus, but it is rare to find general extravasation into the scrotum. Hæmorrhage also results from cutting too freely. In rare cases, after the operation, a permanently bent condition of the penis remains during erection. In University College Hospital, where the operation has been extensively practised, I find from the Reports of the Surgical Registrar that the results are as follows: In 76 cases operated on during a period of five years, there were 4 deaths, one from tuberculous disease of kidneys, lungs, &c., one from pleurisy, one from septicæmia, and one from suppurative nephritis. Perinæal abscess occurred in 8 cases; extravasation of urine in 1, and epididymitis in 4. There was

hæmorrhage in 5, and in 2 the patient was left with permanent chordee during erection.

(For the effects produced on the kidneys by splitting strictures and by internal urethrotomy, see Chap. LXV.)

External Urethrotomy.—The division of the stricture *from without*, by incision through the perinæum, may be performed by two distinct operations: the one being applicable only to those strictures that are pervious to an instrument; the other to those which are impermeable. In the first case a grooved staff is passed through the stricture, and the section is made upon this. In the second case, the Surgeon cuts through the stricture, without any guidance except such as his anatomical knowledge may afford.

Operation for Permeable Stricture.—The first of these operations, introduced by Syme as *Urethrotomy*, and commonly called *Perinæal Section*, is a comparatively simple procedure. The instruments required for its performance are a staff, a No. 8 silver catheter, a pointed scalpel, and a broad director. The staff should vary in size from No. 1 to No. 6, according to the tightness of the stricture; it should be grooved along its convexity, either the whole of the way, or better, merely for the lower third (Fig. 924). The stem is smooth, and of full size, and joins the lower grooved part by a distinct shoulder, which, being passed down as far as the stricture, forms by its projection a guide to the part of the urethra requiring division. In those cases in which there are false passages, a hollow staff of the same size and shape may advantageously be used; the flow of urine through it indicating with certainty its passage into the posterior part of the urethra.

Performance of Perinæal Section.—The operation is performed as follows: The staff having been passed through the stricture until the shoulder rests against it, the patient is placed in the lithotomy position, and the Surgeon, seating himself in front, pushes the scalpel, with the back of the blade downwards, into the mesial line of the perinæum a little above the rectum, and cuts upwards for an inch or more into the raphé. The dissection is carried on very carefully exactly in the median line until the staff is reached, when the knife must be entered into its groove *behind* the stricture, and carried forwards through this. The staff, having been pushed on to ascertain that all is free, must be withdrawn, and a No. 8 catheter introduced, which is to be kept in for forty-eight hours; it must then be taken out, and at the end of eight or ten days the urethra must be dilated by the introduction every second day of a full-sized silver catheter. Urine escapes for some little time by the perinæal incision; but, as this heals by granulation, the flow of fluid gradually lessens and at last ceases entirely.

The principal points to be attended to in this operation are:—

1. To see that the staff is fairly through the stricture, and to be especially careful in determining this if false passages exist.

2. To cut carefully in the median line; where, as Syme has observed, a kind of septum exists even in the deeper structures of the perinæum, and where there can be no danger whatever of dividing any artery of magnitude, which might happen if any lateral deviation of the knife took place. The

Fig. 924.—Syme's Staff for Perinæal Section.

only vessel, indeed, which is at all endangered, is the artery of the bulb ; and this will of course be avoided by carefully keeping in the raphé.

3. To enter the point of the knife behind the stricture, and to divide that by cutting forwards in the groove of the staff.

4. Much difficulty has occasionally arisen in the introduction of the catheter into the bladder after the division of the stricture. This may be avoided by passing a broad director, with the groove turned up, into the posterior part of the urethra after the stricture has been cut, but before the staff is withdrawn. As the catheter is passed down the canal, its point will be guided by this onwards into the bladder.

Where there are more strictures than one, the division of the deepest is usually alone necessary ; the others may be dilated.

Result.—The result of the perinæal section, so far as the life of the patient is concerned, is usually satisfactory ; yet cases have not unfrequently occurred in which a fatal termination has been the consequence, and there is every reason to believe that such cases have been more numerous than the advocates of this operation have been willing to admit. Occasionally, an incurable fistula has been left in the perinæum ; and not unfrequently accidents of a grave though not fatal character, such as inflammatory oedema of the scrotum, perinæal abscess, &c., have supervened.

The whole value of urethrotomy will at last depend on the liability of the stricture to return after its division ; and this point has not as yet been by any means satisfactorily determined. The operation is now rarely practised, being reserved for cases complicated by urinary fistula or perinæal abscess. Its place has been taken by internal urethrotomy in all ordinary cases. Its advocates formerly maintained that it was a permanent cure, but as in all other operations for stricture, the ultimate result depends upon keeping up dilatation of the urethra for some months after the division of the stricture, a catheter of full size being passed once in a week or ten days. If this precaution be neglected, relapse will certainly occur. Against external urethrotomy it has been argued that, like a wound, the incision into the urethra might occasion a cicatrix which would contract, and thus eventually tend still further to lessen the diameter of the canal. But *post-mortem* examination of patients who have died some years after this operation had been performed has shown that the idea is groundless, the cicatrix being linear and scarcely perceptible. In fact, there is a great difference in the result, between cases in which the urethra has been divided transversely and those in which it has been incised longitudinally. In the former, a dense and contractile cicatricial mass is formed ; in the latter, a linear and scarcely perceptible scar.

6. **Excision.**—Complete or partial excision of the stricture, followed in some instances by suture of the divided ends of the urethra, has been practised with some success by Guyon, Keyes, and others. In a considerable number of the recorded cases the stricture has been traumatic in origin. It can only be in very exceptional cases that such treatment is advisable or even practicable. Excision would be available in a case of traumatic stricture in which other treatment had failed or in which an instrument could not be passed, also in some cases of obstinate perinæal fistula. The operation consists in making a median incision in the perinæum exposing the urethra at the seat of constriction. The latter, with the indurated tissue around it, is excised either partially

or completely. A catheter is tied into the bladder, and if possible the continuity of the canal is restored by suture.

Comparison of Methods of Treatment.—Gradual dilatation, carried on with patience and gentleness,—if need be, on account of the irritability of the urethra or the sensitiveness of the patient, with the help of anæsthetics,—will suffice for the cure of the vast majority of strictures; and it rarely becomes necessary for a Surgeon who combines patience with skill to have recourse to those more severe methods of treatment which have been somewhat unduly extolled and too often unnecessarily practised. The urethra is indeed frequently treated as if it were an inert tube, to which the various procedures of rupture, splitting, forcible dilatation, or incision, could be applied with impunity, rather than a highly sensitive canal, very apt to resent, locally or constitutionally, undue violence applied to it.

But, whilst we fully recognize this important point, and hold with Liston that whenever a catheter can be got through a stricture its cure by dilatation is all but certain in the hands of a skilful Surgeon, yet it is certain that cases do occasionally occur in which simple dilatation fails to effect a cure; the stricture being highly contractile, and not allowing expansion beyond a certain point, or relapsing whenever the dilating means are removed. In other cases, also, the patient suffers so much pain and irritation whenever an instrument is passed that he cannot bear the repeated introductions that are necessary, more particularly if the stricture be complicated with perinæal fistulæ or false passages, which render its cure by dilatation tedious and almost impracticable. In such cases as these the Surgeon, being unable to benefit his patient materially by dilatation, must choose between the employment of palliative means or more active measures.

It appears to me that there are four classes of cases, in which more energetic means than simple dilatation may not only be advantageously employed, but are absolutely required:—

1. *Very old dense cartilaginous strictures*, often of traumatic origin, which admit an instrument with great difficulty, and cannot be dilated beyond a certain point, owing to the conversion of the urethral structures into a dense, cicatricial tissue, which neither admits of expansion nor of absorption by the pressure of instruments; and in which a considerable extent—half an inch or more—of the urethra is involved.

2. The same kind of stricture, complicated with *fistulæ* in the perinæum or scrotum, with perhaps considerable plastic infiltration of these parts. In both these classes, I think that the perinæal section is to be preferred, though with the improved instruments of the present day some of the first class may be successfully treated by internal urethrotomy.

3. *Very tight strictures*, accompanied by *excessive sensitiveness* of the urethra; in which each introduction of the instrument is attended with intense suffering and rigors, so that the patient cannot be induced to submit to a proper course of bougies.

4. *Very elastic*, though perhaps *narrow strictures*, that can be dilated readily enough, even up to the admission of full-sized instruments; but which, when the treatment is discontinued, immediately begin to contract again, so that the patient is never out of the Surgeon's hands, and sees no prospect of cure.

In these last two classes of cases, I am of opinion that internal urethrotomy, or the forcible expansion or rupture of the stricture, is the best method of

treatment ; the perinæal section being too severe and dangerous, whilst simple dilatation is too feeble a means of treatment.

Stricture of the Meatus is usually the consequence of destruction of tissue by a chancre. It is apt to be extremely tight, and has a great tendency to relapse. A tight stricture is not uncommonly met with also within an inch of the orifice as the consequence of an intra-urethral chancre, and less commonly of gonorrhœa.

These strictures may be treated by *gradual dilatation* by means of short nail-headed styles of graduated sizes, but this is usually tedious and inefficient. *Division* by Civiale's instrument, introduced shut, and cutting as it is withdrawn (Fig. 925), or in the absence of this, by a common probe-pointed bistoury, will be found the only really advantageous treatment. The incision should be made downwards. It is practically free from danger, as rigors and

Fig. 925.—Civiale's Urethrotome for Stricture of the Orifice, modified.

other constitutional disturbance scarcely ever follow operations on the anterior extremity of the urethra.

Impermeable Stricture.—In order to perform the perinæal section, the stricture must be pervious to a grooved staff, however small this may be ; and this, it might be supposed, would limit materially the cases in which the operation can be performed. But complete obliteration of the urethra cannot take place except as the result of sloughing, usually from injury ; indeed "impermeable" strictures, though frequently spoken of, are very rarely met with. Syme, indeed, denied their existence, and stated that, if urine can escape through a stricture, a bougie can be introduced. A Surgeon may often be foiled in his first attempts to pass an instrument through a very tight stricture. But I believe that, with patience, by attention to constitutional treatment, so as to lessen urethral irritation, and especially by the administration of an anæsthetic, he will usually at last succeed in making an instrument of some kind pass through the very worst strictures. In the first case in which I performed the perinæal section, almost all the urine had for twelve years been discharged through fistulæ in the perinæum and scrotum ; and the principal portion escaped through a large hole on the inside of the left thigh, only a few drops occasionally passing out by the lips of the urethra. No instrument had been passed for four years, though repeated attempts had been made by different Surgeons. Failing to introduce a catheter into the bladder, I kept the patient in the Hospital for two or three weeks, attending carefully to his constitutional condition, but without making any further effort. He was then placed under an anæsthetic, when I succeeded in passing No. 1. The urethra was then dilated up to No. 5, beyond which no instrument could be passed, when the perinæal section was performed. The patient made an excellent recovery, the fistulæ closing, and the urine being discharged by the natural channel. In another case, persevering attempts had

been made for five years to make an instrument enter the bladder, but without success, the stricture not only being excessively tight, but the urethra acutely sensitive ; under chloroform I succeeded in introducing No. $\frac{1}{2}$ silver catheter into the bladder, and speedily cured the patient.

The influence of *Anæsthetics* in facilitating the passage of instruments through apparently impermeable strictures is very marked. Shortly after the introduction of ether as an anæsthetic agent, Liston was going to cut through a stricture that had resisted all attempts made by his most dexterous hand at introducing an instrument into the bladder ; but no sooner was the patient put on the table and rendered insensible, than the No. 8 silver catheter, which had been passed down as far as the stricture, and the point of which was to serve as a guide to the knife, slipped into the bladder, and thus rendered operation unnecessary.

Yet no Surgeon can doubt that cases do occasionally, though rarely, occur, in which, in consequence of extravasation of urine and old inflammatory mischief, the urethra has become so tortuous and narrow, and the perinæum so thickened and indurated, that an instrument cannot be passed through, even though the urine pass out readily. It must be borne in mind that a stricture may be permeable to urine, but impermeable to a catheter, even in the most dexterous hands. It does not follow necessarily that, because a fluid will trickle out of a narrow and tortuous channel, a catheter or solid sound can be passed into it from without. In a case of extravasation of urine following stricture consequent on injury of the perinæum, in which no catheter had been introduced for eight years, it was found after death that, although the urethra had been converted into a mass of cicatricial tissue at the part injured, it was yet permeated by a narrow tortuous passage, through which the urine had escaped.

Hence cases will occasionally occur, in which the perinæal section is not practicable. In the event, therefore, of a stricture being so tight and tortuous that no instrument will pass through it, or where, a portion of the urethra having sloughed away, its canal is obliterated, neither the cure by dilatation nor urethrotomy can be performed, and it may then be necessary to have recourse to incision of the stricture without a guide.

Operations for Impermeable Stricture.—In operating for the relief of impermeable stricture various means have been adopted, the chief of which are, 1, opening the urethra behind the stricture ; 2, opening the urethra behind the stricture and cutting forwards through the constriction ; 3, opening the urethra in front and dividing the stricture from before backwards.

1. **Opening the Urethra behind the Stricture**, or, as it is often called in this country, “Cock’s operation,” is thus performed : The patient having been prepared as for lithotomy, the operator introduces his left forefinger into the rectum. He then takes a broad sharp-pointed knife, which Cock advised should be double-edged, and passes it towards the apex of the prostate, guiding its course by the finger in the rectum. The knife must be passed at one thrust to the apex of the prostate, and great care must be taken that it keeps accurately to the middle line. The external wound is then enlarged somewhat by moving the knife up and down, till the lower angle reaches to about half an inch from the anus. The knife is then withdrawn and a large probe-pointed director with a handle is passed through the prostatic urethra from the wound,

and along this a female catheter, or an instrument of that shape fitted with rings by which it can be securely tied in, is guided into the bladder. The essential points of the operation are to keep accurately to the middle line and to open the urethra as it emerges from the prostate gland. Should the prostate itself be notched no harm will result. The instrument having been passed as above described is tied in and retained for some days or weeks as may be required. In a very large proportion of cases after the irritation of the passage of urine through the narrow stricture has been removed, a certain degree of relaxation will take place, and a few days after the operation it frequently happens that a catheter will pass through the stricture which was formerly "impermeable." If this does not take place, an effort may subsequently be made by some further operative procedure to open up a way in the natural line of the urethra, and should this fail the patient may pass his urine permanently through the fistulous opening in the perinæum. This can readily be kept open by the occasional passage of a flexible bougie, which must be left *in situ* for a few hours. Cock records cases in which the patient passed his water in this way for twenty years or more. The opening being well in front of the prostate the control over the escape of urine is perfect, and the patient's mode of micturition is assimilated to that of the other sex.

This operation is best adapted to those cases in which the patient is suffering from actual retention at the time the Surgeon is called upon to operate. The objection to it is that it does nothing to relieve the stricture unless this should happen to yield after the irritation of the passage of urine is cut off.

2. Opening the Urethra behind the Stricture and cutting forwards.—This operation may be regarded as an extension of the preceding method. It is thus performed: A No. 8 silver catheter is passed down to the stricture; the patient is then tied up as if for lithotomy; and the Surgeon, sitting in front, pushes a bistoury with the back turned towards the rectum into the raphé of the perinæum as far as the apex of the prostate, so as, if possible, to open the dilated urethra *behind* the stricture. He then cuts *forwards* through the stricture on to the point of the catheter, and, having thus opened a passage, endeavours to pass that instrument on into the bladder. This operation, I have no hesitation in saying, is one of the most troublesome in surgery, and I have more than once seen the most skilful operators foiled in their endeavours to accomplish it. The difficulty consists in finding the posterior part of the urethra. When the tissues of the perinæum are hard and gristly from repeated attacks of inflammation and the presence of fistulæ, it is a most difficult matter to dissect through such an altered mass and hit the urethra beyond it, and the difficulty is still further increased by the bleeding, which is often very profuse. Moreover, should the Surgeon find the posterior part of the urethra and cut forwards from it to the catheter in the urethra the chances are that his incision will not follow the line of the urethra, and the fistulous track he establishes between the part of the urethra, in front of the stricture and that behind it will almost to a certainty contract, as the wound heals, to such an extent as to leave the patient little better for the operation.

3. Opening the Urethra in Front of the Stricture and dividing from behind backwards.—This operation, though difficult of performance in some cases, gives better results than any other. Wheelhouse has invented some ingenious instruments which greatly facilitate its performance.

The operation is thus performed: The patient having been secured in the

lithotomy position, Wheelhouse's staff is passed down to the stricture. The end of this is about the size of a No. 8 catheter; on one side it is flattened and grooved, and on the other it forms a small blunt hook, with which the upper end of the "button-hole" incision in the urethra may be drawn upwards. The staff being passed and held with the grooved side forwards, the Surgeon cuts down upon it by an incision about $1\frac{1}{2}$ in. long in the median line and opens the urethra just in front of the stricture. The staff is now pushed out of the wound and turned round, so that the small hook is forwards; it is then drawn upwards so as to catch in the upper angle of the opening, and in this way the urethra is put on the stretch and steadied. If the special staff be not at hand the end of a catheter can be cut down on with almost equal ease. The edges of the slit in the urethra are then seized in artery-forceps and held apart so as to expose the interior of the canal, which can be readily recognized by its smooth shining surface. It will often be found to be convenient to pass a silk suture through each side by which the edges may be held apart, as the forceps are rather apt to get in the way. Oozing having been allowed to cease, the aperture leading to the stricture will usually be found without very great difficulty. The chief trouble in many cases arises from the constant trickling of blood from the upper part of the wound. This may be arrested by plugging it with a small sponge, or by the application of water, at a temperature of about 140° F., which is usually more efficient than ice. Another difficulty may arise from the urethra having been opened too far above the stricture, under which circumstances the incision must be prolonged downwards. If a false passage have been opened instead of the urethra it is recognized by the absence of the smooth pink mucous membrane. The orifice of the stricture must be sought for with a fine probe. Wheelhouse used a small probe-pointed director. In some cases the small director used in slitting up the canaliculus will be found to pass when other instruments have failed. In seeking the true orifice of the stricture every depression must be carefully explored without force. Pressure above the pubes will often cause a slight escape of urine by which the proper orifice may be recognized. When the opening is found and the probe passed, the stricture must be divided along it with a fine knife or tenotome. A small gorget is then passed through the stricture, and along this a full-sized catheter can easily be guided into the bladder. It must be tied in and retained for a few days. The wound may be wiped out with a strong solution of chloride of zinc and afterwards sprinkled with iodoform and filled with iodoform-wool, which may be left undisturbed till the third day, when healthy granulation will usually be found to have commenced. This operation requires care and patience, but it is easier and safer than any other.

In a few rare instances in which failure has attended every other means of passing an instrument through the stricture, suprapubic cystotomy has been performed and a catheter passed from above.

General Results of the Treatment of Stricture.—Whether it is or is not possible permanently to cure a stricture, is a question which has been much debated. The advocates of the various modes of treatment, whether forcible dilatation, internal urethrotomy, external urethrotomy, or electrolysis, have often asserted that by the means they adopt a stricture can be really cured, so that the patient is rid of his disease for ever, and need fear no return. The general opinion, however, of those who have studied this question care-

fully, is that, although a patient can be put into a position in which his stricture need never be a source of danger to him if he occasionally passes an instrument. he cannot be really cured—that is to say, by no means of treatment can a strictured urethra be restored to its normal condition. Every patient, therefore, who has once suffered from a definite organic stricture, should continue for the rest of his life to pass a full-sized instrument not less often than once a month ; otherwise, gradual contraction is almost certain to take place, and the whole treatment will have to be commenced again.

COMPLICATIONS AND RESULTS OF STRICTURE.

Retention of Urine has already been several times described as arising from different causes. Thus, in boys, it arises from the impaction of a calculus in the urethra ; in girls it is usually hysterical ; in old men it is almost invariably the consequence of atony of the bladder or enlarged prostate, alone or combined. In those of middle age, stricture of the urethra is the cause in the vast majority of cases. Retention of urine has a tendency to occur in all tight strictures from the gradual and progressive contraction of the canal. It most usually, however, takes place in consequence of a congestive and spasmodic condition being superadded to the organic constriction. It commonly happens that a patient having a moderately tight organic stricture commits an excess, or becomes exposed to cold and wet, and thus gets such a congested condition superadded, that the urine will not pass at all, or only in such small quantity, and with so much pain and straining, that the bladder cannot be completely emptied. In these cases the retention always eventually becomes complete : the bladder speedily fills, and rises above the pubes ; there is much distress and constitutional disturbance ; and, if relief be not afforded, the distended portion of the urethra behind the stricture will ultimately give way, and extravasation of urine ensue. In these circumstances it becomes imperatively necessary to empty the patient's bladder as speedily as possible.

The **Treatment** varies with the severity of the symptoms and irritability of the patient. If the retention have not continued very long, and if the patient be not very irritable, an endeavour may be made at once to give relief by passing a small catheter into the bladder. In this the Surgeon may often succeed more readily than might have been expected, the stricture frequently yielding before an instrument more easily when there is retention, than when this condition does not exist. Even if the catheter do not enter the bladder, its point or that of a catgut bougie merely being introduced well into the stricture, it will generally happen, as Brodie has pointed out, that, on the withdrawal of the instrument, the urine will follow in a full stream ; but if a sufficiently small catheter be used (in many cases not larger than No. $\frac{1}{2}$ is admissible), the instrument may usually be made fairly to enter the bladder. If the patient be very irritable it is better, before attempting the introduction of the instrument, to give him an enema of a drachm of laudanum in about two ounces of starch, and to put him in a warm hip-bath, when perhaps he may pass water, but if he does not the introduction of the catheter may be attempted, and will generally succeed. Should it still fail, the effect of an anæsthetic should be tried, when it almost invariably may be made to pass without the employment of any great or dangerous degree of force. There are no cases in surgery in which anæsthesia is of more value than in these :

Under its influence it is seldom, indeed, that the catheter will not pass. If a very small catheter only can be introduced, it often happens that the eye is blocked by a clot of blood, and the Surgeon may think he has not entered the bladder. This difficulty is overcome by applying an aspirator to the catheter, which will immediately clear it if it be really in the bladder. It is wiser, therefore, always to have that instrument at hand when attempting to relieve a case of retention of urine. After the catheter has been passed into the bladder it should be left there, being tied in by means of tapes passing from its rings under the patient's thighs, to a bandage that is passed round his waist. A free purge may be administered on the following day, and the patient should be confined to bed. The catheter will be found to be loosened at the end of forty-eight hours, when it should be withdrawn, and the cure by dilatation proceeded with in the usual way.

There are two conditions which in retention of urine may eventually call for operative interference. The first is the necessity for very frequent introduction of the catheter, owing to an irritable state of the bladder. In these cases, it may eventually be thought safer to puncture the bladder and to establish a direct opening either through the perinæum or above the pubes, rather than subject the patient to the constant terror of repeated catheterism, which will end by exhausting him. Every act of catheterism inflicts a certain shock to the system, greater in some, less in others; and if this have to be repeated every three or four hours, less danger will probably result from puncture of the bladder than from the frequent use of the instrument. In these cases the patient cannot allow it to be tied in for the same reason, that of extreme irritability, which necessitates its repeated introduction.

The second condition that calls for operation is a different one, viz. the necessity of relieving retention of urine. For if the Surgeon be unable to introduce a catheter in the ordinary way through the stricture, relief must be given to the over-distended bladder in some other way, lest it or the urethra burst, and extravasation of urine occur. The bladder may be emptied in three ways: 1. By Aspiration; 2. By making an Opening into the Urethra behind and through the Stricture; and, 3. By Puncturing the Bladder above the Pubes.

Forcible catheterism, that is to say, passing a small metal instrument down to the stricture and attempting to drive it on by main force into the bladder, is an unsurgical and dangerous procedure, which should under no circumstances be adopted. Puncture of the bladder through the rectum is also an available method of treatment in these cases which had better be abandoned. It is no doubt easy of performance, but it is attended with obvious inconveniences and not a few dangers. Among the latter may be mentioned septic cystitis, urinary infiltration, pelvic abscess and peritonitis. I also had a case under my care in 1859 in which a widespread emphysematous condition extending to the nates and thighs was produced by the escape of rectal flatus into the areolar tissue after the cannula was removed. The cannula had been in position for five days, and the patient died on the third day after its removal.

1. The use of the **Aspirator** is on the whole the simplest and safest means of affording immediate relief in a case of retention of urine due to stricture of the urethra, in which the Surgeon altogether fails to pass an instrument into the bladder. The perforating trochar of the aspirator should be passed

directly into the bladder above the pubes. The operation is a simple one, and with a little care is perfectly safe. The chief points are not to thrust the needle too deeply, to direct it well behind the pubes, and gently to withdraw it before the whole of the urine has escaped, so as to prevent the emptied bladder from collapsing upon and being wounded by its point (see p. 757, Vol. II.). After relief has thus been afforded the patient should be confined to bed, and means be taken to subdue the congestion and spasm which, complicating the organic stricture, have probably been largely instrumental in causing the attack of retention. A morphia suppository should be introduced into the rectum and a brisk saline aperient given. After a few hours another attempt may be made to pass a catheter; if this fail and the patient be still unable to relieve himself, aspiration may be repeated twice or even three times when the bladder has refilled.

It must be clearly understood that aspiration is undertaken merely with the object of affording temporary relief to the distended bladder, and thus allowing time for further attempts at catheterization. If the latter still prove unsuccessful, even after aspiration has been performed three or four times, the case must be treated as one of impermeable stricture, Wheelhouse's operation being as a rule the best method to adopt (p. 1200).

2. Tapping the Bladder above the Pubes, in cases of retention from stricture, is occasionally practised. It differs essentially from aspiration in this respect, that a cannula, or a soft catheter introduced through it, is left in the bladder for drainage, whereas in aspiration the distension of the bladder is relieved and the needle at once removed. This operation, which has been discussed at p. 1152, is undoubtedly easy of performance, and sufficiently safe, though not free from the danger of infiltration of urine into the tissues around the puncture, and of the inconvenience of a fistulous opening being left. The only advantage which this treatment presents is that it is a simple method of giving perfect rest to the urethra, and thus allowing its condition to become more favourable for the passage of an instrument into the bladder. As soon as this can be done the stricture is dilated or divided, and after the introduction of a full-sized catheter *per urethram* the cannula above the pubes is removed and the opening allowed to close.

3. Opening the Urethra behind the Stricture.—This operation is rarely required as an immediate treatment in cases of retention from stricture. There is, however, one class of cases in which Cock's operation should certainly be performed—those in which retention is complicated by commencing extravasation of urine or perinæal abscess. If there be a brawny tender swelling in the perinæum it may almost certainly be concluded that suppuration has occurred around the urethra behind the stricture or that the extravasation of a few drops of urine has taken place. Under these circumstances the incision into the dilated urethra behind the stricture will not only relieve the patient from the distress and danger of the retention, but will also afford a free exit for any extravasated matters. The mode of performing the operation has already been sufficiently described at p. 1200.

Extravasation of Urine is one of the most dangerous and fatal results of unrelieved retention. This accident may occur in consequence of rupture of the dilated portion of the urethra which is immediately behind the stricture. It then takes place suddenly, the patient, while suffering from retention, feeling something give way during a violent effort at micturition, and at the same

time there is a sense of some relief, as if he were emptying the bladder, followed by a hot and burning throbbing pain in the perinæum.

In other cases the process is more gradual, and is preceded by the formation of an abscess in the immediate neighbourhood of the urethra, most probably commencing in one of the lacunæ or glands opening into it. The abscess bursts into the urethra, and its cavity is subsequently distended with urine at each act of micturition; finally its walls give way, and general extravasation takes place. In some cases it is probable that the abscess arises from a very limited extravasation of urine into the tissues in the immediate neighbourhood of the urethra, consequent upon ulceration of the mucous membrane behind the stricture. In these cases the signs of perinæal abscess, presently to be described, precede the extravasation often for some days.

The part of the urethra that gives way is almost invariably the membranous portion of the canal, just between the layers of the triangular ligament, where it is weak, being least supported by surrounding structures, and usually most dilated and attenuated by the pressure to which it has been subjected. The extravasated urine afterwards finds its way through the inferior layer of the triangular ligament, where it is perforated by the urethra, and so beneath the deep layer of the superficial fascia of the perinæum, by which its course is afterwards directed. The fascia is firmly attached across the perinæum to the free border of the triangular ligament and, along each side, to the rami of the ischium and pubes, as far upwards as the pubic spine, from which point its attachments are continued outwards along Poupart's ligament to the crest of the ilium. The extravasated urine, therefore, uniformly takes a course forward into the perinæum and scrotum, and upwards upon the external organs of generation, the groins, and the anterior abdominal wall; so that it ascends contrary to gravity rather than soaks back into the more dependent parts of the body, as it would do, were it not for the particular connexions of the fascia that have just been alluded to. I have, however, known the superficial fascia to give way, and the urine, then gravitating backward, to give rise to extensive sloughing in the ischio-rectal fossæ and about the nates, denuding the rectum.

The **Local Effects of Extravasated Urine** that has become acrid, decomposed, and concentrated by long retention, are most deleterious upon the tissues with which it comes into contact. It acts as a most intense irritant on all that it touches. The vitality of whatever portion of areolar tissue it infiltrates is quickly destroyed; the tissue becoming converted into a kind of putrid stringy slough, intermixed with and soddened by a quantity of fetid dark-coloured acrid pus and urine. The ravages of extravasated urine are often extensive; the urethra giving way suddenly behind the stricture, the fluid is driven with all the force of the over-distended bladder into the perinæum, and thence rapidly finds its way through the scrotum upwards. Rapid swelling and infiltration, partly urinous, partly inflammatory, take place in the scrotum and penis; these parts become enormously distended, red, and œdematous. The skin is speedily affected, becoming of a dusky-red or purple colour, and then falling into a state of gangrene, sometimes with emphysema. In this way the testes may become denuded and the cords exposed. It is remarkable, however, if the patient survive these destructive effects, with what rapidity repair goes on in this region. It is seldom that infiltration extends higher than the

groins, or the anterior portion of the abdominal wall ; but it may reach the costal cartilages before proving fatal.

The **Constitutional Disturbance** is always very great. At first there is high fever, with a rapid full pulse ; but the symptoms speedily assume the form met with in acute septic poisoning. The tongue becomes brown and dry ; there may be vomiting ; the pulse becomes small and very rapid : muttering delirium sets in, ending in insensibility, and death quickly follows.

The *Treatment* must be active and immediate, and consists in making a free exit for the urine infiltrating the tissues, and preventing further extravasation by establishing free drainage of the bladder. As soon as any pain and throbbing, with diffused swelling, occur in the perinæum, with redness and œdema of the scrotum, a deep median incision should be made so as, if possible, to open the dilated urethra behind the stricture. The patient having been placed in the position for lithotomy, the Surgeon should introduce his left index-finger into the rectum, so that the gut may not be wounded, and then pushing a long sharp-pointed bistoury deeply in the raphé of the perinæum, cut upward to a sufficient extent into the extravasation, and in the direction of the urethra. A catheter should then, if possible, be introduced, secured in the bladder, and left unplugged, with an india-rubber tube attached ; in this way no further extravasation can occur, an outlet will be afforded to matters already effused, and the urine will escape by the aperture thus made. Should the case not be seen until extravasation has spread widely, a free incision should be made not only into the perinæum, extending into the urethra, but also into the scrotum on each side of the septum, into the penis, and wherever else swelling is observed. The sole chance of safety for the patient is in making these free incisions, through which the parts may, to a certain extent, empty themselves. However extensive the infiltration and serious the mischief may be, we need not despair of the patient if a free outlet can be obtained for the acrid and putrescent urine ; and in order to secure this, the infiltration must be followed by incisions as high as it extends. The parts must be covered with some warm and moist antiseptic dressing, the best being boric acid lint moistened with warm boric acid lotion, and at the same time they should be well dusted with iodoform. If this be not at hand the surface may be greased with carbolic oil (1 in 10), or terebene and oil and fomentations made of oakum wrung out of boiling water may be applied. These applications are cleaner than poultices, and should always be preferred. The patient will often experience great relief from frequent hot hip-baths, Condry's fluid or boric acid being added to the water. In this way the parts can be most thoroughly cleaned without pain to the patient.

If the patient survive the immediate impression upon the system produced by the gangrene and the urinary infiltration, he must be prepared to go through a severe trial to his constitutional powers, in the separation of the sloughs, the profuse discharge, and other sources of irritation that are set up. During this period he will require abundant support—the brandy-and-egg mixture, ammonia and bark, with any nourishment that he can take ; and much attention should be paid to the removal of the sloughs, to providing a ready outlet for discharges, and to keeping the patient as clean and as free from all local irritation as possible.

As soon as possible the stricture must be dealt with by one of the means already described, and thus the fistula in the perinæum allowed to heal.

Perinæal Abscess.—By perinæal abscess is meant a collection of pus in the perinæum situated under the deep layer of the superficial fascia of this region. It is the confinement of the pus by the fascia which gives these abscesses their special character. Owing to the attachments of the deep fascia which have just been described, the pus formed in connexion with the urethra is shut off from the ischio-rectal fossa, just as extravasated urine is. If the abscess be left unrelieved, it may burrow widely around the bulb and along the urethra before it reaches the surface by perforating the fascia. It is very important, therefore, that such abscesses should be opened early.

The chief forms of perinæal abscess met with are the following :—

1. **Abscesses arising from Suppuration in a Lacuna or Follicular Gland.**—These have already been described as an occasional complication of gonorrhœa. They are met with also in stricture. They may point slowly towards the surface, without actually communicating with the urethral canal. In other cases they open into the urethra, and then run the same course as abscesses commencing from the canal.

2. **Abscesses commencing from Ulceration in the Urethra behind a Stricture.**—These arise in the dilated pouch behind a tight stricture. As before stated, the mucous membrane at this part is thickened and opaque, and often pigmented, showing evidence of chronic inflammation. The openings of the ducts are dilated, sometimes giving the whole surface a reticulated appearance. The ulceration commences in one of the hollows thus formed. The inflammatory consolidation of the surrounding tissues prevents general extravasation ; but the pressure during micturition and the constant presence of retained urine causes gradual extension of the cavity till a distinct abscess is formed discharging imperfectly into the urethra. Such an abscess slowly extends till it reaches the surface. It then bursts, its cavity contracts to a narrow channel, and thus a urinary fistula is formed. At any period before it bursts superficially, its wall may be ruptured during a violent effort at micturition, and diffuse extravasation of urine may result.

3. **Abscesses from Injuries by Instruments.**—These occasionally arise from false passages made with a catheter or bougie ; they may also follow forcible dilatation or internal urethrotomy. More rarely they result from inflammation and ulceration of the mucous membrane around an instrument tied into a tight stricture. These abscesses usually form rapidly. If resulting from a false passage behind a tight stricture, they may lead to extravasation of urine ; but under other circumstances, as there is a free passage through the urethra, this is not likely to occur. If the injury is in the bulbous or spongy portion, the pus may burrow forwards along the urethra under the accelerator urinæ, and appear at the root of the penis in front of the scrotum.

4. **Suppuration of Cowper's Gland** is an occasional cause of a perinæal abscess. It may occur from the irritation of a stricture, but far more commonly it is met with during the acute stage of gonorrhœa. The gland can at first be felt as a tender knot on one side of the middle line near the bulb. This gradually increases and becomes more tender, and at last fluctuation is felt. This form of abscess can be recognized, if seen early, by its situation, and by the fact that it is distinctly on one side of the middle line. At a later period it may burrow widely round the bulb and in the perinæum, so that its exact origin cannot be determined. It usually causes some difficulty in micturition.

5. **Prostatic Abscesses** may, as before stated (p. 1138), occasionally point in the perinæum.

It will be seen that there are two distinct classes of perinæal abscesses: those that communicate with the urethra, and those that do not. The former usually end in urinary fistula.

The **Characters of a Perinæal Abscess** are those of a hard, rounded, elongated or oviform mass, situated in front of the anus, extending along the urethra, or perhaps occupying to some extent one side of the perinæum. Fluctuation is not to be felt so long as the pus is bound down by the superficial fascia; when it bursts beyond its limits, then that sign may be met with. But so long as it is under the fascia the abscess will be found to be surrounded by so dense a mass of indurated tissue, and so tightly bound down, that fluctuation, or even elasticity, is not appreciable by the most practised finger.

Treatment.—The use of local sedatives, fomentations, and poultices is of no avail in these cases. When once pus has formed in this situation it must be freely evacuated. No good can possibly come of delay, and every possible harm may result from the infiltration of pus among the important tissues of this region. The Surgeon must not wait for fluctuation, but when once the hard mass has fully formed must make a free incision into it. For this purpose he must keep in the mesial line, or as close to it as possible; for in all perinæal incisions "*medio tutissimus*" must be his motto.

Urinary Fistulae commonly form in the perinæum and scrotum, as the result of abscess in these regions communicating with the urethra; occasionally, however, they are met with in other situations, as in the groin, the anterior abdominal wall, or the inside of the thigh. They usually communicate with the membranous portion of the urethra, but occasionally occur anterior to this. In number they vary considerably; when occurring in the scrotal and penile portions of the urethra, they are usually single; but when in the perinæum, they are often rather numerous, several apertures being occasionally met with about the perinæum, scrotum, and nates. In one case Civiale found as many as fifty-two. Their size also differs considerably; some admitting only the finest probe, while others are large cloacæ. In a case under my care, the patient had a tunnel of this kind in the groin that would readily admit three fingers. They are usually tortuous, elongated, and narrow; sometimes constricted externally and more widely dilated behind. The surrounding parts are greatly condensed; the whole of the scrotum and penis is enormously enlarged, indurated, and almost cartilaginous in structure. The urine may escape almost entirely through the fistulae, scarcely any being discharged through the urethral orifice; or there may be but a slight exudation from the fistulous openings.

The **Treatment of Urinary Fistula** varies according as it is complicated with stricture, and as it is situated in the anterior or the posterior part of the canal.

If there be a stricture, this, as the cause of the fistula, must be treated either by dilatation or by the perinæal section. If the stricture be not very tight and hard, dilatation commonly succeeds; the instrument being introduced every second or third day, until the urethra is dilated to its normal size, when the fistulous tracks will in most cases close. In some instances, however, the frequent introduction and withdrawal of the catheter is a source of irritation, and then it had better be left in. When this practice is

adopted, a moderate-sized elastic catheter should be used. If this be too small, the urine will flow between it and the sides of the urethra, and thus escape through the fistulæ; if too large, it stretches the urethral orifice of the fistula injuriously.

If the stricture be very tough and irritable, the better plan is to perform urethrotomy at once. In the majority of instances, internal urethrotomy appears to me to be the safest and simplest procedure, and I have very advantageously practised it in such cases. But if the fistulæ be very numerous, so as to riddle the perinæum and scrotum in all directions, the better plan is to perform perinæal section. In this way we not only divide the stricture, and thus at once remove all obstruction, but give a free exit to the urine, which, instead of escaping by narrow and sinuous passages, finds its way out readily through the new aperture that has been made, and this will eventually granulate and heal by the second intention.

The fistulæ, especially if small and recent, will sometimes heal kindly enough after the removal of the obstruction; but if extensive, old, and cartilaginous, they are of course little disposed to repair; and although the cause that in the first instance gave rise to them may be removed, yet they constitute an independent affection which requires special treatment.

The special treatment for urinary fistula must vary according to the size of the track, but more particularly with regard to the part of the urethra with which it communicates—whether it be a *Perinæal*, a *Scrotal*, or a *Penile* fistula. But in all cases, and wherever it be situated, there is one most important point to be attended to, viz. never to let the fistula be disturbed or irritated by the passage of urine over or through it, or it will never heal. Hence the urine must always be drawn off with the catheter, which the patient should be taught to pass for himself.

If the fistula be *Perinæal*, and of small size, a probe coated with melted nitrate of silver, or a wire made red-hot in the ordinary way, or by the galvanic current, and passed down it occasionally, may cause its contraction. If the fistula be single and large, its edges should be freely rubbed with nitrate of silver, or deeply pared and brought together by sutures, after which the urine should be drawn off, whenever required, by a catheter. If the fistulæ be large and numerous, it will be better to pass a grooved director down the principal ones, and slit them up so as to throw the several sinuses into one.

When the fistula is *Scrotal*, it often requires to be laid open, and to be made to granulate from the bottom, when it may be found to communicate with a large sloughy and ill-conditioned cavity in this situation.

When *Penile*, the fistula is usually much more troublesome to heal; its edges are thin, and the track is short and shallow. **Urethroplasty** may in such cases be practised with advantage. Operations of this kind require for their success very careful management and minute attention to detail; they very commonly fail in consequence of a small quantity of urine or of mucus escaping through the wound, and thus interfering with union of its lips.

In order to prevent this accident, which is fatal to the success of the operation, the urine must be drawn off with a catheter every third or fourth hour. Should this, however, not be practicable, a full-sized gum-catheter should be tied into the bladder, and the urine drained away through an india-rubber tube attached to it.

Urethroplastic operations may be varied according to the seat and extent of the fistulous opening. If the fistula be in the *perinæum*, the parts around being thickened and indurated, its closure may often be induced by freely and deeply paring the edges, and then bringing them together with deep silver wire sutures.

When the fistula is *scrotal*, the edges should be freely pared, and the parts around widely dissected up so as to form large and thick flaps of cellulo-cutaneous tissue, which may be brought and held together by metallic sutures. In this way, if union be not obtained throughout the whole length of the fistula, it may be to a partial extent; and, after a time, a second or a third operation will complete the cure.

When the fistula is *penile*, the difficulties in effecting closure become immensely increased. This is owing to the thinness of the integumental structures and the absence of subcutaneous areolar tissue in this region, so

Fig. 927.—Urethroplasty.
Nélaton's Operation: First Method.

Fig. 928.—Urethroplasty.
Nélaton's Operation: Second Method.

that there is not sufficient thickness of the parts for ready plastic union. In these cases, the Surgeon has a choice of four operations:—

1. Nélaton has recommended the following procedure: The edges of the fistula having been pared, the skin around, to the extent of about an inch, should be dissected up subcutaneously through an opening made below the fistula, the edges of which must then be brought together by a few points of suture. The displacement of the skin covers in the aperture in the urethra and causes granulations to spring up, by which the fistula is closed (Fig. 927).

2. The edges of the fistula having been pared and the skin separated widely, lateral incisions may be made so as to take off all tension, and a strip of india-rubber may then be passed underneath the flaps of skin, in order to prevent contact with urine from disturbing the adhesions (Fig. 928).

3. Ricord, recognizing the fact that the occasional intrusion of a drop of

urine between the freshened edges of the integuments brought together to close the fistula is the most common cause of failure of union, recommended that, in those cases in which a perineal or a scrotal fistula happens to co-exist with a penile one, a catheter should be passed through the former into the bladder and left there during the whole of the operative procedures that are adopted for the closure of the penile fistula. Should no fistula exist in the perinæum, he proposed to puncture the bladder, and to keep it emptied in this way until the penile fistula has been closed by one of the preceding operations, and then to allow the opening to close spontaneously; or, if it were situated in the perinæum, to adopt surgical means for its occlusion.

4. Le Gros Clark successfully practised the following operation: Having pared the edges of the fistula, he made a transverse cut through the integuments of the penis, about an inch in length, above and below it. He then dissected up the flaps of skin so bounded, and brought them together by means of clamps or the quilled suture. By this operation a wide raw surface from each side is brought into contact, instead of a mere raw edge of cut

integument, and there is consequently a greater chance of successful union resulting (Figs. 929, 930).

In all operations of this kind union will be promoted by keeping the part constantly bathed with a concentrated cold solution of boric acid. In this way decomposition of any mucus or urine that may accidentally find its way to the wound is prevented, and at the same time the lotion is so unirritating that it does not interfere with union. The lotion is best applied by means of a piece of boric acid lint, which must be frequently wetted and changed. If the urine can be efficiently kept from the wound, a dry dressing of iodoform or salicylic wool will be found the best.

Stricture of the Female Urethra is rare. When it occurs, it is usually near the external orifice, and is most commonly the result of gonorrhœa, injury during labour, or syphilis. The symptoms are the ordinary ones of irritability of the bladder, frequent desire to micturate, and some difficulty or delay in doing so.

The *Treatment* consists in the dilatation of the orifice by means of Hegar's dilators.

URINARY VAGINAL FISTULÆ.

Fistulous communications between the urinary passages and the vagina commonly arise from sloughing produced by long-continued pressure upon the anterior vaginal wall during labour. They may also occur from malignant disease.

Varieties.—Urinary vaginal fistulæ are mainly of two kinds: *Vesico-Vaginal* and *Urethro-Vaginal*.

Vesico-vaginal fistulæ are the more common; they are usually situated high up in the vagina, communicating with the base of the bladder. They may be very minute or may form a large gaping orifice.

Urethro-vaginal fistulæ, occurring between the urethra and the vagina, are usually of small size, and linear.

Results.—The existence of a urinary fistula is always a source of the greatest discomfort to the patient. The dribbling of urine, usually continuous but occasionally intermittent, when the opening is near the fundus of the bladder, gives rise to irritation and excoriation about the external parts, and causes a penetrating ammoniacal odour to hang about the patient. The precise seat and extent of the opening can be determined in the case of large fistulæ by digital examination, combined with the passage of a sound into the bladder. In the case of small perforations or those high up, careful examination should be made with Sims's duck-bill speculum and retractors, the patient being placed in the semiprone or genu-pectoral position. It is often useful to draw down and fix the cervix during the examination. In doubtful cases the injection of milk into the bladder will determine the presence or absence of a fistula.

Treatment.—When the fistula is recent, very small, and especially if urethro-vaginal, it may be closed in a few cases by touching it with the

Figs. 981 and 932.—Knives for Paring the Edges in Vesico-Vaginal Fistula.

galvano-cautery. When it is large, however, its cure can be accomplished only by paring the edges and bringing them together with sutures. Before the operation the bowels should be freely opened by castor-oil and by an enema. It is of the greatest importance that the field of operation should be properly exposed and well illuminated, and for this purpose preliminary dilatation of the vagina is often required. A large but short Fergusson speculum is a useful addition to the duck-bill specula and retractors usually employed. The patient may be placed in the dorsal, lateral prone, or genu-pectoral position, whichever is the most convenient. The edges of the aperture are now to be freely pared. This is best done by seizing them with a hook-forceps or a double hook, and dissecting off the vaginal mucous membrane to the extent of about a quarter of an inch all round, by means of a fine small scalpel or angularly

set knife (Figs. 931 and 932). Care should be taken that the angles are well freed from cicatricial tissue, and that the vesical mucons membrane be not wounded. When the fistula is near the cervix it may be advantageous to incise the anterior lip or even to excise a wedge-shaped portion, so as to give free access to the fistulous opening. After the edges have been freely pared they are to be brought together with silver-wire sutures, passed by means of a hollow needle (Fig. 933), or by fine flat Hagedorn's needles. Silver wire or fine and strong silk is the best material for the sutures. The needle should be introduced about $\frac{1}{3}$ to $\frac{1}{2}$ an inch from the freshened edge, and brought out

Fig. 933.—Hollow Suture Needle.

through the corresponding point on the opposite side without transfixing the vesical mucons membrane. Between the deep sutures superficial ones should be placed so as accurately to approximate the surfaces; it is best to tighten the superficial sutures first and then the deep ones. Whenever possible the edges of the fistula should be brought together transversely to the long axis of the vagina. Trendelenburg and others have sutured vesico-vaginal fistulae through a suprapubic opening into the bladder, but it is probable that this method will only be required in very few and exceptional cases.

After-treatment.—The vagina after the operation is washed out with 1 in 2000 perchloride lotion, and iodoform dusted in the wound. Iodoform gauze is then lightly packed into the vagina, to be removed together with the stitches about the eighth day.

Sims's retention catheter (Fig. 934) may be introduced into the bladder for the first 48 hours; after this a catheter must be passed every four hours; catheterization should be continued until two to three days after the stitches have been removed. The bowels should be kept closed for the first three days; after this they may be opened with castor-oil and kept open every day with medicine if necessary.

Fig. 934.—Sims's Catheter.

TUMOURS OF THE URETHRA.

Polypi of the male urethra are rare, if we exclude the small polypoid masses of granulation tissue which are sometimes detected with the endoscope in cases of chronic gleet (p. 1159). A small granular florid mass is sometimes met with just within the orifice of the canal. It should be snipped off with a fine pair of curved scissors.

Bryant has recorded a case in which he removed a myomatous polypus as large as a haricot bean from the floor of the prostatic urethra, through a perinæal incision. The patient, sixty-three years of age, had suffered from increasingly severe attacks of hæmaturia for six years, with increased frequency of micturition. The prostate, which was greatly enlarged, decreased after the operation, and the symptoms were cured.

The **Vascular Caruncle** of the female urethra is met with as a small bright-red pedunculated or sessile tumour, situated most commonly at the lower margin of the urethral orifice. These tumours grow slowly and seldom attain a size larger than that of a raspberry. They bleed freely when touched, and give rise to very marked symptoms, of which the most important are bleeding, painful micturition, and pain during coitus.

Thus the symptoms may closely resemble those of stone, so that patients labouring under this affection are often sounded on the supposition of the existence of a calculus.

In structure the vascular caruncle resembles that of erectile tissue, and the surface is papillary and covered with stratified epithelium. The mode of origin of these tumours is somewhat doubtful. Pozzi suggests that they arise from the extension of the hymen, which as he has shown, forms a ring around the urethral orifice, and sometimes remains as a small tongue at its lower margin. Prolapse of the mucous membrane of the urethra may give rise to a very similar appearance.

The *Treatment* consists in snipping off the little vascular growth with scissors and destroying the base with the fine point of a Paquelin's cautery. If the tumour be small and pedunculated this may be done under the influence of cocaine.

Primary Squamous Carcinoma of the male urethra is extremely rare. Writing in 1890, Marcus Beck was able to collect only ten cases in addition to one recorded by himself; and in only five of the cases was the nature of the disease confirmed by microscopic examination. From a consideration of these cases Beck gives the following description of the disease: "Primary cancer of the urethra occurs in men over fifty, who have most commonly suffered from some previous disease of the canal, usually gonorrhœal stricture. The most prominent symptom is the gradual formation of a hard lobulated mass round the urethra. Micturition becomes increasingly difficult, and is almost always very painful, far more so than in simple stricture. Hæmorrhage, especially before and after micturition, seems to be a common symptom. As the growth extends the corpora cavernosa and their crura become implicated, and the disease advances past the scrotum into the penile portion of the urethra. The glands in the groin enlarge, and the patient becomes cachectic in appearance. The passage of instruments is from the beginning difficult, and is always followed by bleeding. The next stage of the disease is the formation of a foul cavity containing blood-stained purulent fluid in connexion with the urethra. The discharge from this may be recognized escaping from the urethra. As the cavity enlarges a perinæal abscess forms, which reaches the surface, bursts, and leaves a fistula. The carcinomatous growth then extends to the skin and superficial structure along the line of the fistula." In Beck's case at University College Hospital the perinæal tumour was thought to be an inflammatory mass around a small urethral abscess behind a stricture. With the endoscope a tight stricture was seen, and on only one occasion was a filiform bougie passed

into the bladder. The nature of the disease was detected when perinæal section was performed ; a ragged cavity being opened the dense tissue around which presented the typical naked eye and microscopic characters of squamous carcinoma. The patient left the hospital at his own wish three months later and was not heard of again. In Mikulicz's case the disease was removed together with the whole penis and its crura, but recurrence occurred in four months.

CHAPTER LXXII.

DISEASES OF THE PENIS AND SCROTUM.

DISEASES OF THE PENIS.

Complete Arrest of the Development of the Male Sexual Organs is of very rare occurrence. I have seen only one instance of it. This was the case of a man aged 22, in whom the penis and scrotum were perfectly formed, but not larger than the organs of an infant a few months old. No distinct testes could be felt, but there was some thickened structure in the scrotum which felt like an undeveloped testis. The prepuce was long. There was very little hair on the pubes. This person had sexual desires, and, in fact, had become engaged to be married. He told me that he had erections, when the organ became about an inch or an inch and a half long, and that there was occasional emission of a glairy fluid. He was fair, fresh-coloured, round-faced, fat, and had smooth rounded limbs, more like those of a stout girl than of a young man. His voice was weak and feminine in tone. He led a sedentary indoor life, but said that he was strong and capable of ordinary physical exertion.

CONGENITAL MALFORMATIONS.

Congenital Absence of the Penis has been recorded in a few rare instances ; it may be associated with other abnormalities. **Double Penis** is a pathological curiosity. In three cases, one of which was recorded in this country by Ernest Hart, the malformation was associated with the existence of a third lower limb attached in front of the anus ; urine escaped through each penis, and the scrotum also was double.

Adhesion of Penis to Scrotum.—I have once met with the curious condition in which the penis is tied down to the scrotum, so as to lie in a deep sulcus between the testes. In this case the raphé of the scrotum appeared to be continued in a narrow rather firm band upwards to the under surface of the penis, so that this organ was always bent downwards. The patient, a man of 30, passed his urine downwards, apparently from the under surface of the scrotum : during erection the penis curved up in a semicircular form, the convexity upwards, the glans being tightly tied down to the scrotum by the narrow tense band continued up from the raphé. In fact, the condition of this organ was very like that which is met with in the tongue when “tongue-tied.” This malformation was remedied by cutting through the frænum which tied the penis down, and thus liberating the organ.

Hypospadias consists in a cleft condition of the under surface of the penis. Up to the tenth week of intra-uterine life the external organs of generation are alike in the male and female. At this time the uro-genital

aperture forms a narrow slit, wider behind than before, at the anterior extremity of which is a small eminence representing the rudimentary penis or clitoris. In the female the uro-genital aperture remains unclosed and the external folds of integument forming its lateral boundaries enlarge, forming the labia majora which cover the vascular bulbs corresponding to the corpus spongiosum of the male. These remain separate and distinct, but a small isolated portion becomes united in the middle line, forming the glans of the clitoris. In the male the two sides of the uro-genital aperture unite, forming the scrotum, and the bulbous and spongy portions of the urethra. At the same time the small eminence, which in the female becomes the clitoris, develops into the penis. The vascular bulbs, which in the female remain separate, unite in the male, forming the bulb of the corpus spongiosum. In the female no corpus spongiosum exists in the clitoris, the glans being an isolated nodule of erectile tissue. In the male the erectile tissue is continuous around the urethra from the bulb forwards.

Hypospadias consists in an arrest of the union along the middle line, and in proportion to the degree of the malformation the male organs come more closely to resemble the female in appearance. Hypospadias appears in three degrees. In the simplest form the glans is cleft along its under surface, the prepuce also showing a corresponding gap. In the second degree the corpora cavernosa and glans are well developed, but the urethra is cleft to the root of the penis, and thus resembles a large clitoris. The under surface shows a furrow in the line of the urethra, usually covered by a moist mucous membrane. Between the glans penis and the point at which the urethra terminates a firm dense band of fibrous tissue is often present, somewhat resembling in hardness and tension the cicatrix of a burn. In these cases when erection takes place the organ assumes a crescentic shape, with the convexity upwards, the tense hard cord that has just been mentioned stretching across its arc like the string of a bow, thus rendering connexion impossible, and the sufferer practically impotent. The third and most extreme form of hypospadias is when the scrotum also is cleft and the urethra opens in the perinæum. This is usually accompanied by imperfect development of the penis, and by retained testicles. It is this malformation that has erroneously been considered to be an example of hermaphroditism. The cleft empty scrotum resembles the labia of the female, and the diminutive penis may readily be taken for a large clitoris.

Hypospadias affects only the parts in front of the membranous portion of the urethra, and consequently never leads to incontinence of urine.

Treatment.—The first degree of hypospadias requires no treatment, the cleft glans being not even an inconvenience. Intermediate degrees between the first and second require treatment only if the urethra is so short that the semen cannot enter the vagina during connexion, or if there is a tight band beneath.

In the second degree of hypospadias, the first step is to dissect away the firm fibrous band which prevents complete erection. Some months after this has been successfully accomplished, and when the scars have become supple, the attempt may be made to close the urethra. In order to do this successfully, it is necessary to provide an epithelium-covered lining for the new urethra. Many methods have been suggested for doing this, but by far the best is that of Anger, which is an adaptation to hypospadias of Thiersch's operation for epispadias. It is thus performed : An incision is made parallel

to the groove representing the urethra, and half an inch from its right margin: a transverse incision from each end of this is made up to the edge of the urethral groove. The flap thus marked, which we will call the right flap, is then dissected up, leaving it attached along the margin of the urethral groove. A similar flap is then raised on the left side, but on this side the incision is carried along the left margin of the urethral groove, and the flap turned outwards, its attached edge being in the position corresponding to the free edge of the right flap. The right flap is now turned over so that its skin surface forms the lining of the new urethra. A number of fine stitches are then inserted in the following way: The needle is first passed through the base of the left flap from the skin surface, next through the free edge of the right flap from the raw surface towards the skin; then it is made to catch the left edge of the urethral groove, and finally it is passed again through the base of the left flap. In this way the edge of the right flap is held in position, and the stitches can be removed from the surface. When these have all been passed they may be tightened. A similar number of stitches are then passed through the free edge of the left flap, by which it is attached to the skin of the penis at the outer edge of the raw surface from which the right flap was raised. The raw surfaces of the two flaps are thus brought closely into contact, and an epithelial lining formed for the new urethra. During the healing, a catheter must be tied in, and the bladder drained. A small fistulous opening will usually be left at the lower end, which must be closed by a subsequent plastic operation. Several successful cases of this operation have been recorded, and it seems to be by far the most efficient of the many methods. The third degree of hypospadias admits of no treatment. The operation should not be performed on young children, as the parts are too small.

Epispadias.—The upper surface of the penis is less frequently fissured. The malformation commonly occurs in conjunction with extroversion of the bladder, but a few cases are recorded in which the penis only was cleft. This condition may be remedied by Thiersch's operation above described.

Phimosis.—The prepuce is not unfrequently the seat of malformation or disease. The condition of it in which it is so much elongated that it extends beyond the glans, while at the same time it is so much contracted that it prevents the proper exposure of this portion of the organ, is termed *phimosis*. This may be either congenital or acquired.

In **Congenital Phimosis** the penis is often somewhat atrophied, and the development of the glans is prevented by the pressure of the narrow prepuce. The constricting band which prevents the retraction of the foreskin is always situated at the junction of the skin and the mucous membrane. Without marked contraction of the preputial orifice it may be impossible to retract the prepuce on account of its adhesion to the glans. In the majority of cases a long foreskin is simply a source of local inconvenience; but it may become a source of disease. Thus, in children, retention of the sebaceous secretion—"smegma preputii"—becomes a source of local irritation and inflammation from decomposition. The irritation thus kept up (Fig. 935) favours the early development of the habit of masturbation. In some cases the preputial orifice is so tight as to interfere with the discharge of the urine, which passes from the urethra into a kind of pouch between the glans and prepuce, distends this structure, and is then squeezed in a fine jet or in a scattered sprinkling

stream through the narrowed preputial orifice ; and irritability of the bladder, often presenting symptoms simulating calculus, may thus be set up. In very rare instances a fatal result has ultimately followed as the result of changes in the kidneys caused by the persistent obstruction. Calculous concretions may form between the glans and the prepuce in such cases as these. Whishaw, of Fyzabad, removed no fewer than 426 calculi, varying in size from a pin's head to a small bean, from this situation in a native of India, 60 years of age, who came under treatment for what appeared to be a large tumour of the end of the penis, the true nature of which was not detected until in removing it the knife grated against the contained calculi. Various affections of the genito-urinary organs in children, such as incontinence, intermittent flow of urine, hæmaturia, priapism, &c., have been shown by Bryant to be caused by congenital phimosis. The straining in micturition may give rise also to hernia and prolapse of the rectum. Hydrocele of young children will also be found to be very frequently associated with phimosis. Sayre has pointed out the important fact that reflex paralysis and various forms of spastic contractions, chiefly of the lower limbs, are due to the same cause, being readily curable by circumcision. In addition to these I have seen general spasmodic affections in children resembling chorea, resulting from congenital phimosis. At more advanced periods of life I have known it to be a cause of sterility, the semen being retained under the tight prepuce until erection had completely subsided. Congenital phimosis especially becomes a source of inconvenience in after-life if any gonorrhœal or venereal disease be contracted, as it renders exposure of the diseased part difficult or impossible, and interferes with the necessary treatment. In the opinion of some Surgeons, cancer of the penis, if not directly occasioned, is at all events predisposed to, by congenital phimosis.

Fig. 935.—Irritated
Congenital Phi-
mosis.

Acquired Phimosis usually results from repeated attacks of inflammation, or of specific disease in the part, giving rise to solid œdema, or to false hypertrophy of the prepuce.

In elderly men, phimosis will sometimes slowly come on as a consequence of the irritation set up by cracks, fissures, or superficial ulcerations round the preputial orifice, which becomes narrowed, so as to prevent the glans from being uncovered. It may occur in gouty or diabetic subjects as the result of repeated attacks of balanoposthitis (p. 1228). The preputial mucous membrane becomes thickened, and can be felt like a broad band under the loose and possibly slightly œdematous integument of the prepuce. This condition is a source of much irritation and annoyance, and requires relief by dilatation or by circumcision.

Treatment.—Every child who has a congenital phimosis ought to be circumcised ; and even those who, without having phimosis, have an abnormally long and lax prepuce, would be improved greatly in cleanliness, health, and morals by the same operation. It would be well indeed if the custom of Eastern nations, whether it be regarded as a religious rite or only as a time-honoured observance, were introduced amongst us. Phimosis, when not congenital, must be treated in accordance with its cause : thus, if it have resulted from inflammation, that must be subdued ; if from venereal disease, that must be remedied, when perhaps the contraction and elongation will gradually subside.

If, however, the phimosis, though acquired, be permanent, it should be subjected to operation.

A long foreskin, if a source of annoyance to an adult, may easily be remedied by keeping it constantly drawn back. At first the tendency for the prepuce to slip forwards must be overcome by wrapping a piece of dry lint round it and securing it by an elastic band, which must be just tight enough to keep it in position. After a few weeks the foreskin will retain the retracted position, and after a year or so will be found to have undergone considerable diminution in size.

Operations for Phimosis may be conducted on three plans: the elongated and contracted prepuce may be dilated, or slit up, or circumcision may be performed.

1. **Dilatation of the Prepuce** by the expansion of a pair of forceps introduced through the orifice cannot be recommended as good treatment for congenital phimosis. It often causes so much swelling that circumcision becomes necessary, and as the administration of an anæsthetic is required it is much better to proceed at once to that operation. In the acquired phimosis of old men I have found that dilatation may speedily be effected by the introduction of a two-bladed dilator, and in certain cases in which any cutting operation is contra-indicated this may be the only available treatment.

2. **Slitting up of the Prepuce** upon its upper surface is an objectionable procedure, leaving the prepuce of abnormal length, and more or less fissured and knobbed. In all cases I prefer circumcision, as giving the most satisfactory result.

3. **Circumcision** is by far the most satisfactory treatment for phimosis, whether congenital or acquired. According to the Hebrew rite the operation is performed on the eighth day after birth, as follows:—The child being held on the lap of an assistant, the operator draws the foreskin slightly forwards, and then grasps it just in front of the glans by drawing it through a slit in a silver guard. This is not held perpendicularly, but is inclined from above slightly forwards and downwards, so as to avoid cutting the frænum, and to slice off the prepuce in an oblique manner. This is done by one stroke of a broad round-ended knife. The mucous membrane is then torn open between the finger and thumb along the dorsum of the penis, and is turned back so as to be brought into contact with the cut edge of the skin. A strip of dry lint is then twisted round the organ in the sulcus behind the glans, so as to keep back the mucous membrane, and also to restrain hæmorrhage by its pressure. Union is perfect in a few days. The operation is very rarely attended with any ill consequences. I have, however, seen it in one case followed by fatal erysipelas, and have heard of another instance in which death occurred from hæmorrhage.

The *Operation* is most conveniently performed as follows:—A general anæsthetic should as a rule be administered, although in exceptional circumstances cocaine may be used. Except in the case of young children hæmorrhage during the operation may be restrained by a tape or a piece of fine rubber tubing, tied tightly round the root of the penis. The Surgeon then draws the prepuce forwards until the portion of it which corresponds to the back of the glans is brought just in front of that structure. In young children especially care must be taken not to remove too much skin. The projecting prepuce is then seized just in front of the glans with a pair of narrow-bladed

polypus forceps or sinus forceps, which is held firmly by an assistant. The forceps are not held vertically, but are inclined slightly forwards below. With one sweep of a bistoury the Surgeon cuts off all that portion of the integument which projects beyond the forceps, which are then removed (Fig. 936). It will now be found that he has removed only a circle of skin, but that the mucous membrane lining it still tightly embraces the glans; this he slits up along its dorsal surface as far as the corona, by introducing the point of a pair of scissors at the preputial orifice. In doing this care must be taken not to introduce the lower blade of the scissors into the urethra. The mucous membrane is then turned back completely from the glans, any adhesions being separated and all smegma removed. The excess of mucous membrane is cut away with scissors, so that only a narrow strip remains around the base of the glans. If a tourniquet has been used this is now removed, and any vessels which spurt, usually one on each side of the penis and one or two in the frænum, are twisted or ligatured with the finest catgut. The edges of the

Fig. 936.—Circumcision in the Adult.

skin and mucous membrane are then adjusted with a sufficient number of fine sutures, the first of which should be passed opposite the frænum and the raphé of the penis. In young children many Surgeons dispense with sutures altogether, but a more satisfactory result is obtained by inserting at least four or six. If fine catgut is used it will be absorbed, and thus save the pain of taking them out, or if horsehair sutures are inserted very close to the edges of the skin and mucous membrane, and tightly tied, they usually work out in the course of a week. In young children the simpler the dressing the better. A convenient method consists in wrapping a narrow strip of butter-cloth spread with boric ointment around the line of the wound, and keeping it in place by a narrow strip of gauze fixed at its end with collodion to the abdominal wall at the root of the penis. In the adult an antiseptic gauze or wool dressing may be applied with a narrow bandage. This may be left unchanged for four or five days. Primary union usually occurs, except perhaps in the position of the frænum, where perfect apposition is not so readily obtained. The dressing is best removed by thoroughly soaking it in warm boric lotion.

There is usually a good deal of swelling of the mucous membrane about the *frænum*, and some solid oedema usually remains for some weeks after the operation. This gradually subsides, and a linear cicatrix remains, which causes the patient no inconvenience.

Paraphimosis.—In *paraphimosis* the prepuce has been forcibly drawn back behind the glans, which becomes strangled by the pressure exercised by the preputial orifice, so that the parts cannot be replaced in proper relation to one another. This accident principally occurs in boys, or in individuals who have naturally a tight prepuce, and who, on uncovering the glans, find it difficult to get this part of the organ back. This difficulty is speedily and greatly increased by the swelling from congestion that is set up in the constricted glans. It may also result from inflammatory swelling of the prepuce due to *balanoposthitis*, and other causes in cases in which no phimosi previously existed.

The **Treatment** is simple. The Surgeon should first try to reduce the swollen organ. He may often succeed in doing this by seizing the body of the penis between the index and middle fingers of each hand, and endeavouring

Fig. 937.—Reduction of Paraphimosis.

Fig. 938.—Incision in Operation for Paraphimosis.

to draw the prepuce forwards, at the same time that he compresses the glans between the two thumbs and pushes it back (Fig. 937). Should reduction not be effected in this way, the constricted and strangulating preputial orifice must be divided. In doing this, the Surgeon will observe that the glans is separated from the body of the penis by a deep and narrow sulcus, which is especially evident on the upper part of the organ. This sulcus, which is overlapped on one side by the skin of the penis, and on the other by the swollen mucous layer of the prepuce, corresponds to the inner margin of the preputial orifice; and it is by the division of this, in which the stricture is situated, that immediate relief will be given. This operation may readily be done by drawing the glans and swollen prepuce forwards, then passing the point of a narrow-bladed scalpel into the sulcus on the dorsum of the penis, and making a perpendicular incision about one third of an inch in length through the integuments at the bottom of the groove (Fig. 938). In consequence of the great stretching of the parts, the incision will immediately gape widely; so that, instead of being longitudinal, it will appear to be transverse; and then reduction of the glans may readily be effected.

Balano-posthitis.—*Balanitis*, or inflammation of the glans, and *Posthitis*, or inflammation of the prepuce, rarely occur independently of each other. Simple balano-posthitis is very frequently set up by accumulation of smegma and dirt beneath a long, tight prepuce, but the most acute form occurs as a complication of gonorrhœa or soft sores. The prepuce is much swollen, infiltrated, and reddened, and, while the inflammation lasts, continues in a state of phimosis; there is a muco-purulent discharge, and, especially when the glans is affected, a good deal of irritation and smarting. The glands in the groins are often tender and swollen, and occasionally suppurate.

A chronic form of balano-posthitis is apt to occur in gouty subjects, and has already been mentioned as a cause of acquired phimosis. Jacobson mentions two cases in which there was also Dupuytren's contraction of the palmar fascia, the gouty nature of which is generally accepted. The inflammation of the prepuce which occurs in diabetics is probably due to the irritation of the urine.

Treatment.—The disease requires to be treated on general principles. In the slighter forms the application of lead lotion, with the internal administration of salines, will usually suffice. In the severe forms, in which there is a purulent discharge from the orifice of the prepuce, and in which, in spite of constant fomenting, the prepuce cannot be retracted, it should be slit up along its dorsal surface in order that the exact state of affairs may be seen. In many cases it will be advisable to complete the circumcision; and this operation is also advisable if the patient is subject to repeated attacks of the simple form. In the gouty form circumcision may also be required, but in that due to diabetes operation must be avoided, unless the inflammation is intense and sloughing seems likely to occur.

Herpes of the Glans and Prepuce is characterized by the formation of small vesicles and minute ulcers upon the mucous membrane of this region, attended with much smarting and itching, and occurring chiefly in gouty persons with an irritable mucous membrane.

Treatment.—This slight affection is often very rebellious to treatment. In many instances local means alone will not suffice; for, though relief may be obtained by powdering the part with the oxide of zinc, or by using slightly astringent and cooling lotions, yet no permanent benefit will be derived unless constitutional treatment be adopted. Salines should be administered, and, if the patient is gouty, may be combined with colchicum and alkalies. For the cure of recurrent attacks Hutchinson speaks highly of arsenic.

Persistent Priapism, lasting for many days, is occasionally met with, as the result in most cases of venereal excess, and more especially of violent coitus during intoxication. The erection of the penis is not accompanied by any sexual desire, but is attended with great pain, a sense of weight about the perinæum, much anxiety, and constitutional disturbance. The organ is hard and unyielding. The pathology of this condition is obscure. By some it has been considered to be the result of extravasation of blood into the corpora cavernosa; by others, to depend on sympathetic or reflex nervous irritation. The effect of treatment would lead to the inference that the latter view is correct. Incisions into the corpora cavernosa to let out the blood supposed to be extravasated have been productive of no good, whilst the erection has rapidly subsided under full doses of bromide of potassium.

Gangrene of the Penis.—Sloughing of the integuments of the penis, to

a greater or lesser extent, not unfrequently occurs in persons of broken constitution as the result of inflammatory phimosis, simple or gonorrhoeal (Fig. 939), or of syphilitic phagedæna, and indeed the glans and body of the organ may often be extensively destroyed by the latter cause. These various forms of the disease have already been described.

True *idiopathic gangrene* of the penis is, however, a very rare disease; and Demarquay, who specially directed attention to it, found but few instances of it in the records of surgery. It has chiefly been met with in people of advanced age or of broken constitution, who, whilst suffering from some local affection of the organ, have been attacked by acute febrile disease, such as typhoid or small-pox, or have become the subjects of pyæmia. In some cases it is probably embolic. The disease, when affecting the body of the penis, is often fatal—possibly by hæmorrhage on the separation of the slough. When the glans only is attacked, the prospect is better. But in either case mutilation of the organ to a serious extent will result.

Fig. 939.—Sloughing of the Prepuce, and Protrusion of the Glans.

Fig. 940.—Warts on the Glans and inner surface of Prepuce, which is slit up.

The *Treatment* of gangrene of the penis presents nothing special, with the exception of restraining hæmorrhage by means of the actual cautery, and preventing or repairing loss of substance in the urethral wall, if it be invaded by the disease and involved in the destruction resulting.

Hypertrophy of the Prepuce occasionally occurs as the result of chronic irritation or disease; it is usually of limited extent, and requires no special treatment; but in some instances it may become so extensive as to require operative interference. The hypertrophy is due to solid œdema of the prepuce and body of the penis, the organ being greatly enlarged and club-shaped. In these cases circumcision, with the excision of a V-shaped piece from the dorsum of the prepuce, will be found to give a satisfactory result. Vidal has figured a case in which the penis had attained such an enormous size that it reached to below the knees, and was as large as a thigh. This monstrous growth was successfully excised.

Warts on the penis have already been described. They may attain a very large size, as in Fig. 940, and are best treated by being snipped off with curved scissors.

Horny Excrescences have been observed to spring from the glans penis.

The most remarkable case of this kind on record is one by Jewett of Connecticut. It was that of a young man, in whom, after operation for congenital phimosis and the removal of warts, a horn grew from the left side of the glans penis, and attained a size of three and a half inches in length by three-fourths of an inch in diameter at the base. It could be handled and cut without pain, and the patient "was accustomed to amuse the inmates of the ward by lighting the end of the horn and allowing it to burn." It was excised, and did not return.

Sebaceous Cysts are occasionally met with, usually on the under surface of the penis or prepuce. **Dermoid Cysts** are very rare; they have been found in the raphe on the under surface of the penis along which the two halves unite to close the urethra.

Fibrous Tumour of the Penis.—The penis may be the seat of fibroid and other tumours. The accompanying drawing (Fig. 941) is an illustration of

Fig. 941.—Fibroid Tumour of the Penis, successfully removed.

Fig. 942.—Warty Carcinoma of the Penis.

one springing from the fibrous tissue of the corpora cavernosa which I removed some years ago from the under surface of the organ.

Sarcoma of the Penis is very rare. It appears to commence in the cavernous tissue. The only available treatment is amputation.

Carcinoma of the Penis.—The form of cancer met with in the penis is *Squamous Carcinoma*. It usually springs from the sulcus behind the glans, and thence invades the neighbouring portion of the organ. It always commences in the anterior extremity of the penis, affecting the body of the organ only by extension from the original starting-point. It appears in two forms, either as a flat tubercle or as a distinctly papillary growth. When it commences as a tubercle it appears as a hard pale reddish-white mass situated on the glans or between the prepuce and the glans. This increases in size, and extends deeply into the organ. At last a crack forms and allows a serous discharge to exude, which usually becomes very fetid. Ulceration then rapidly takes place. Sometimes the disease appears to be very distinctly localized; but after its removal it will usually be found to infiltrate the organ for a considerable distance.

The papillary form at first presents the appearance of ordinary warts (Fig. 942). It grows rapidly, and a deep-seated indurated base can be felt beneath

it. Ulceration soon sets in, with abundant foul discharge. At first the distinction from a simple growth is not easy to make, but the flat hard base infiltrating the glans will usually indicate its nature.

Cancer of the penis occurring under a long foreskin soon leads to such enlargement of the glans that the prepuce cannot be drawn back. It then causes a globular enlargement over which the skin of the prepuce is tightly stretched, and a foul serous discharge, often tinged with blood, escapes from the orifice. Finally the distended foreskin may give way and the fungating cancerous growth project through an ulcerating aperture in it. The glands in the groin are early affected.

Causes.—It has been supposed, and with some show of reason, that congenital phimosis predisposes to the affection; probably by confining the secretions, and thus keeping up irritation of the part. Hey found that, of 12 patients with this disease who came under his observation, 9 had congenital phimosis; and Travers states that Jews, who are circumcised, are seldom subject to this affection. But as they are a limited community in this country, and as the disease is rare, we cannot draw any conclusive inference from this observation. It is, however, very probable that the papillary form of the disease often arises from the local irritation resulting from the accumulation of the secretion under a long foreskin. Chronic balanoposthitis often occasions a condition of the mucous membrane of the glans and prepuce closely resembling that seen in chronic superficial glossitis, and this undoubtedly predisposes the part to the development of carcinoma. The nodular form of the affection, however, may occur frequently in individuals who have not suffered from any source of irritation; of this I have seen several instances.

Diagnosis.—Carcinoma of the penis requires to be diagnosed from *papillomata*. This may usually be done by comparing the indurated state of the malignant with the soft and lax condition of the non-malignant affection. From an *indurated chancre* of the glans, the history of the case and the way in which it is influenced by treatment will enable the Surgeon to make the diagnosis.

The **Treatment** of cancer of the penis will vary according to the nature and extent of the affection. If the growth have originated in the prepuce, it may be possible, if the case be seen early, to remove the disease completely by circumcision. Should the growth involve the glans or body of the penis, the treatment must be conducted on the principles that guide us in the management of malignant affections elsewhere, viz., to remove the diseased organ at as early a stage as possible, whilst the affection is confined to it. In the penis this may readily be done by a simple operation that is nearly devoid of danger. I believe that amputation of the penis for cancer is more successful in its results than is the extirpation of malignant growths from most other situations. In some of Hey's cases, which continued under his observation, there was no recurrence of the disease for several years. I have seen several patients who, after a lapse of six or eight years, have continued free from recurrence; and I have also seen a gentleman in whom no return had taken place after more than twenty-five years. The fact is, that we hear of those cases in which a recurrence takes place; but those patients who remain free from a return of the affection do not divulge their infirmity; and it is exceedingly rare in hospital practice to find a patient come back with recurrent cancer in the stump of the penis, which he would certainly do if relapse took

place. In those cases in which the operation is not successful, it has usually been delayed too long, the disease having already implicated the lymphatic glands in the groin.

Amputation of the Penis is best performed with the knife. The operation should always be performed towards the root of the organ, so as to be well clear of the disease. Before proceeding to operate means must be taken to restrain hæmorrhage. This is best done by encircling the root of the penis tightly with a piece of india-rubber tubing which is secured with catch forceps. The operation may be done in various ways, but the *circular method* is perhaps as efficient as any. The penis being drawn well forwards, a circular incision is made round it with a bistoury, dividing the skin only. The corpora cavernosa are then cut carefully through from the dorsal aspect, care being taken not to wound the corpus spongiosum. If necessary a full-sized catheter may be introduced to define more clearly the limits of the urethra. The part of the penis beyond the section of the corpora cavernosa being drawn well forwards, no difficulty will be found in separating these from the corpus spongiosum. Finally the corpus spongiosum is cut through half to three-quarters of an inch nearer the glans than the incision through the corpora cavernosa. The bleeding is then arrested. There are usually five arteries requiring ligature: the dorsales penis, one in each corpus cavernosum, and one in the septum. In securing these, trouble is not unfrequently experienced in consequence of the retraction of the stump that is left. The danger of hæmorrhage scarcely exists if the tape or the tourniquet have been properly applied before the operation, as every artery should be secured before the compression is taken off. The projecting urethra is then slit up with a pair of scissors along the dorsal aspect. It is then spread out and attached by catgut sutures to the skin below and to the corpora cavernosa above. In this way the contraction of the urethral orifice, which is often a most serious source of inconvenience and even of danger to the patient after amputation of the penis, may with certainty be prevented. Hilton, who first pointed out the necessity of providing against this accident, recommended that the urethra should be slit along its under aspect, but if this be done the urine is directed downwards between the legs during micturition, while if the slit be made towards the dorsal aspect it is often projected somewhat forwards, and the patient can thus make water with less inconvenience. In performing the operation care must be taken that the skin is not dragged too much forwards, lest sufficient covering be not left. After the operation is finished the cut spongy tissue should be wiped over with a solution of chloride of zinc (gr. 40 to ʒj.), and the stump must be covered with a piece of lint moistened in boric acid or some other antiseptic. After passing water the parts must be well bathed with some antiseptic solution. In this way septic infection, which may readily occur in so spongy and vascular an organ, may be prevented.

The *flap method* also gives good results. A rectangular flap is raised from the dorsal half of the penis, and whilst the flap is held back the penis is transfixed with a fine straight bistoury between the corpora cavernosa and the corpus spongiosum, and a short lower flap cut from above downwards and forwards. The corpora cavernosa are next cut through vertically, opposite the angles of the flaps, and the urethra is dissected out from the lower flap. After arresting the bleeding, the upper flap is turned down over the stump, and the urethra brought out through a small puncture made in it.

The flaps are united with sutures, and the urethra is slit up and adjusted with sutures to the edges of the opening in the upper flap.

If the amputation be performed too high up infiltration of urine may take place into the scrotum, and to prevent this, it may be safer to introduce an elastic catheter after the operation, and leave it in for a few days.

If the glands in the groin are distinctly, but not too greatly, enlarged, an attempt should be made to remove them at the same time as the amputation of the penis is performed.

In a case extending too far back to allow the performance of the ordinary operation, Pearce Gould successfully removed the disease by dividing the scrotum and dissecting away the whole organ as far back as the crura, leaving an opening in the perinæum through which the patient subsequently passed water. This operation has since been repeated in many cases with success. It has been recommended to remove the testes at the same time, as they are somewhat in the way during micturition, but this seems hardly necessary.

If after amputation of the penis much inconvenience arises from the urine being passed downwards between the legs, it may best be avoided by following Ambrose Paré's advice of adapting a funnel, which may be made of metal or ivory, to the pubes over the stump, and thus carrying the urine clear of the person.

DISEASES OF THE SCROTUM.

Hæmatoma of the Scrotum.—In rare instances, as the result of an injury or severe straining effort, an extravasation of blood occurs in the loose cellular tissue of the scrotum. The importance of the condition lies in the fact that it is likely to be mistaken for hæmatocele of the tunica vaginalis, in which the blood is often effused around as well as within the serous cavity (p. 1246).

McCarthy has recently recorded an unusual case of this so-called "extra-vaginal hæmatocele." The patient was seventy-four years of age, and was admitted to the London Hospital on account of a large globular swelling in the left half of the scrotum. Above, the swelling presented a tubular prolongation which extended into the inguinal canal, and over its lower part the skin was discoloured. The tumour fluctuated but was not translucent. The swelling had repeatedly been tapped, and, according to the patient, clear fluid had been drawn off.

There was no history of any other injury, nor of cough or violent exertion. The swelling was tapped and 10 ounces of dark blood-stained fluid drawn off. In ten days the sac had refilled, and a smaller quantity of similar fluid was withdrawn. A month later, the swelling having again filled, an incision was made, and a large cavity containing dark fluid and lined with fibrine was opened. In this cavity lay the testicle, with its tunica vaginalis distended with 2 ounces of clear fluid. The operation was followed by rapid recovery. The condition present was evidently due to gradual alterations in an extravasation of blood, which possibly in the first instance was the result of tapping the hydrocele. McCarthy points out that, with the exception of the slight discoloration of the skin, the signs were those of a hydrocele, opaque either from the thickness of its walls or the character of its contents.

Inflammatory Oedema of the scrotum is an erysipelatous inflammation of this region, and derives its chief peculiarity from the circumstance of its giving

rise to great effusion into and swelling of the areolar tissue of this part and of the penis, with a tendency to rapid sloughing, by which the integument may become affected to such an extent as to lay bare the testes. This disease usually originates from some local source of irritation, as fissures, cracks, or urinary extravasation (Vol. I., p. 957). There is a peculiar form of "inflammatory oedema" of the scrotum and penis, which is apt to occur as a sequela of small-pox and scarlet fever; rapid and extensive infiltration of the parts occurs, with a tendency to speedy gangrenous disorganization of the areolar tissue and skin.

The **Treatment** consists in elevating the scrotum, fomenting it well, and making early and free incisions into it, particularly at the posterior and dependent parts of the scrotum and penis, with the view of relieving the tension and thus preventing the liability to slough. Should this occur, the case must be treated on ordinary principles, when cicatrization will speedily ensue, however extensive the denudation of parts may be. The constitutional management must be conducted with special attention to the maintenance of the patient's strength.

Elephantiasis of the Scrotum has already been described at p. 42.

Squamous Carcinoma occasionally affects the scrotum; and as it occurs principally in chimney-sweeps, it has appropriately enough been termed *Chimney-sweeps' Cancer*. The disease appears to arise from the irritation of the soot lodging in the folds of the scrotum (Vol. I., p. 1054). It may also occur in workers in tar and paraffin. Butlin, who recently lectured on this subject before the Royal College of Surgeons, does not think that there is sufficient evidence to show that the generally accepted opinion that chimney-sweeps' cancer is much rarer now than formerly is founded on fact. He concludes that the rarity of the disease on the Continent is due to the adoption of a special costume by foreign sweeps which protects them from the soot.

The disease commonly commences as a tubercle or wart, which after a time cracks and ulcerates, and assumes the ordinary characters of a carcinomatous ulcer. It gradually spreads, and may at last involve the greater part of the scrotum, and even invade the testis. After a time the inguinal and pelvic glands may be affected; and the patient, if deprived of his covering of soot, will be found to be cachectic-looking.

Butlin has made the interesting suggestion that certain rare instances, in which a carcinomatous growth in the inguinal glands has occurred without any evidence of the existence of a primary tumour, may be explained by supposing that the primary growth has failed to develop although it has caused infection of the lymphatics.

The *Treatment* consists in excising widely the diseased portion of the scrotum, provided the inguinal glands be not involved to such an extent as to render any attempt to remove them inadvisable. The disease has a great tendency to recur, and the recurrent growth may arise, not in the position of the original tumour, but in some other part of the scrotum, the skin of which is usually thickened and warty. Recurrence in the glands is not uncommon.

CHAPTER LXXIII.

DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS.

THE testes are, in the foetus, situated in the lumbar region below the kidneys, and by a gradual transition they descend into the scrotum a short time before birth. In its descent the testicle is preceded by a pouch of peritoneum, the processus vaginalis testis, which normally becomes afterwards closed above, and forms the tunica vaginalis. Although much doubt exists as to the exact way in which the descent of the testicles is brought about, it seems probable that the most important agent in the process is the *gubernaculum testis*. The existence of this fibro-muscular structure has long been recognised, but our knowledge of its development and relations has been largely increased by the recent researches of Lockwood and others. Above, the gubernaculum ends in fibres which are attached to the vas, the epididymis, the body of the testis, and the peritoneum of the back of the abdomen. Below, the fibres have been traced to the abdominal wall in the position of the internal abdominal ring, whence others pass along the inguinal canal, some ending on the pubes, and others in the scrotum and perinæum. Lockwood has also described a band, which can usually be found in the earlier months, passing outwards into Scarpa's triangle.

It is probable that the processus vaginalis as well as the testis itself owes its descent to the action of the gubernaculum, the upper fibres of which pass to the peritoneum. Under normal circumstances it is supposed that the testis is drawn to the position of the internal abdominal ring by the abdominal fibres of the gubernaculum. It is then drawn along the inguinal canal by fibres passing to the pubes, and finally drawn into the scrotum by the scrotal assisted by perinæal fibres.

The descent of the testis may merely be delayed so that, instead of the gland being in the scrotum at birth, one or both do not leave the abdomen until some time afterwards; in other cases the testis is permanently arrested at some spot along the line of its normal descent, whilst very rarely the organ leaves its proper path and strays to the perinæum or thigh.

A **retained testis** may continue to lie within the cavity of the abdomen; it may be arrested at the internal abdominal ring; it may remain in the inguinal canal, or may project just beyond the external abdominal ring, without properly entering the scrotum. The testicle is often very movable, and may be slipped upwards completely inside the abdomen and downwards to the lower end of the canal.

When the testis is completely retained, no other symptom exists except the absence of the organ from its normal position; but when it occupies the inguinal canal it is often the seat of pain, due no doubt to the compression to which it is exposed. It may also, as has been stated at p. 867, become complicated with, or be mistaken for, a hernia, and may present many diagnostic difficulties.

In rare instances the testis misses the scrotum and passes into the perinæum, where it usually lies close to the anus. The explanation of this malposition is probably to be found in the fact that a prolongation of the fibres of the gubernaculum can usually be found passing to the perinæum. Still more rarely the testis has been known to escape by the crural canal on to the thigh.

There is a very important question connected with malposition of the testis, viz., Is the organ when undescended prolific? Curling and others were of opinion that it is not, but more recent observations tend to show that the organ is at first functionally active, but that it "ages prematurely." In some cases of double cryptorchism spermatozoa have been found in the seminal fluid, whilst in other cases they have been absent; and it would appear that this depends largely upon the age of the patient, and whether or not the testicle has been the seat of attacks of inflammation. The compression to which a testicle is exposed in the inguinal canal is harmful to its functional activity; the organ is often smaller than normal, and is liable gradually to undergo degenerative changes. In the present state of our knowledge of this subject, it may be concluded that a man with both testicles retained is by no means necessarily sterile, but that he is likely to become so at a comparatively early age.

Not only is a testicle retained in the inguinal canal especially liable to inflammation from slight injuries, but should gonorrhœal epididymitis occur, the symptoms are intensified by the compression of the surrounding tense structures. There is also a liability to severe acute symptoms due to torsion of the cord, and it is probable that a retained testicle is more prone to malignant disease than an organ in its natural position.

Inflammation of the Testis in the Inguinal Canal may sometimes take place, even in adults, when the organ has not descended through the external ring, giving rise to a train of somewhat puzzling symptoms, which closely resemble those of strangulated hernia; with which, however, it must be borne in mind that it may be associated (p. 867). On examination, a large irregular tumour, in some parts hard, in others soft, very tender, and occasioning a sickening sensation when pressed upon, will be found in the situation of the inguinal canal. There is usually a tendency to vomiting, with some constipation, and colicky pains in the abdomen. On examining the scrotum it will be found that the testis on the affected side is absent; and on passing the finger into the external ring, the organ can be felt to be lodged in the canal. In consequence of the proximity of the peritoneum to the inflamed testis, this membrane occasionally becomes involved in the morbid process; and, as the result of the constriction of the tendinous and aponeurotic tissues in the situation, sloughing has occasionally occurred. Either of these conditions may lead to a fatal termination.

Torsion of the Spermatic Cord was first described by Nicoladoni in 1885, and since the publication of cases in this country by Whipple and Bryant the condition has received considerable attention, and must be regarded as one of great practical importance. The accident is especially liable to occur when the testicle is imperfectly descended and freely movable. There is frequently a definite history of some exciting cause, such as a jump or muscular effort, which is rapidly followed by severe pain, often accompanied by vomiting. Almost immediately a tumour makes its appearance in the groin, and thus the close resemblance of the symptoms to those of a strangu-

lated hernia is obvious. When, however, as rarely happens, the affected testicle is in its normal position, the case is more likely to be mistaken for one of acute inflammation of the organ. Of 18 recorded cases in which the diagnosis made is stated, 11 were thought to be strangulated hernia, 2 inflammation of the testicle, and in 5 only the true nature of the condition was suspected or definitely recognized. Bryant and others have pointed out that the vomiting is rarely so severe or persistent as in hernia, whilst the general symptoms of strangulation of intestine are absent. The chief difficulty would therefore consist in distinguishing the case from one of strangulated hernia in which the sac contains omentum or in which the whole lumen of the bowel is not obstructed.

The rapid development of a swelling in these cases is due to the sudden engorgement of the testis with blood, the gland being described as having the appearance of a ripe plum. There may also be an effusion of blood-stained fluid into the tunica vaginalis.

Treatment.—In one case recorded by Gifford Nash the condition was diagnosed an hour and a half after the appearance of the first symptom and the half twist of the cord was undone by manipulation, the swelling of the testis and epididymis disappearing almost at once. As a general rule, however, the case is not seen until such treatment is impossible, even if the diagnosis be clear. An incision is therefore necessary, and removal of the affected testicle is probably always the best course to adopt. If the testicle be in the inguinal canal the necessity of removal is obvious, but even if the testicle be in its normal position and the torsion can be relieved, atrophy will probably follow, as in Bryant's case, in which this treatment was adopted, or actual sloughing may take place. It is interesting to note that in Nash's case, mentioned above, the testicle subsequently became considerably smaller than the other.

Treatment of Misplaced Testis.—No treatment is required for a testicle retained in the inguinal canal if the patient is an infant and the condition is not complicated with hernia. When, however, the patient is older—preferably between eight and ten years—an operation may be undertaken with the object of transplanting the gland into the scrotum, and thus relieving the inconvenience of a testicle in the groin, and possibly preventing its subsequent atrophy. The difficulties of the operation are twofold. In the first place it may be found difficult or even impossible to free the testicle sufficiently to allow it to be drawn downwards into the scrotum; the vas deferens is long and lax, but the vessels may be short, and firm adhesions present. Secondly, when the testicle has been brought down into the scrotum the difficulty is to keep it there.

The operation consists in making an incision over the inguinal canal and extending it downwards to the scrotum. The testicle is exposed and carefully separated from the surrounding structures, great care being taken not to damage the vas. As a rule the tunica vaginalis is found open into the peritoneum, and must be divided above the testicle. The testicle can, as a rule, now be gently drawn into the scrotum, the tissues of which are separated to receive it. Various methods have been devised with the object to keeping the testicle in its new position.

The simplest consists in passing a single silk suture through the tissues at the bottom of the scrotum and the tunica albuginea. This, however, often

fails to prevent the testicle being gradually drawn upwards again. Another plan consists in attaching a silk suture to the testicle, passing the two ends out through the bottom of the scrotum, and knotting them over a pad of gauze included in the dressing, or, as Watson Cheyne has suggested, to a light wire frame which fits round the scrotum. After about ten days the projecting part of the silk is cut off. Horsley has obtained good results by loosely fixing the upper end of the testicle by means of a silk suture to the periosteum covering the ramus of the pubes. The silk is passed with a curved needle on a handle, care being taken not to wound the crus penis. In any case the external abdominal ring must be sufficiently closed with sutures.

If the testicle lies in the perinæum it can usually be transplanted into the scrotum without great difficulty. It must be dissected out, and left attached by the cord only. An incision is then made into the scrotum, the testicle placed in its proper position, and secured by a fine stitch. The treatment of retained testis complicated with inguinal hernia has already been considered at p. 874.

Retroversion of the Testicle is not very uncommon. The organ is completely turned round, so that the epididymis is placed in front. In a case of this kind which I had an opportunity of examining after death the epididymis and vas deferens were considerably larger than natural. If a hydrocele form in such a case, it will be seated behind the testis.

NEURALGIA OF THE TESTIS.

A painful or irritable condition of the testicle may occur without any actual disease of the organ ; the pain being seated either in the epididymis, which is the part naturally the most tender, in the body of the testis, or extending along the cord to the loins and groins. It is usually paroxysmal, and is accompanied by great tenderness, and commonly by some fulness of the organ, which feels soft and flaccid ; but it is difficult to make a proper examination, on account of the agony that is induced by touching the part. This disease occurs chiefly in young men of a nervous temperament, and is frequently associated with great mental despondency, sometimes amounting to a suicidal tendency.

The **Causes** are obscure : in many cases the disease appears to be connected with a neuralgic temperament, but in others it is associated with some dyspeptic disorder, or may be dependent upon local irritation ; thus, external piles, or the pressure of a varicocele, will often give rise to it. In middle-aged or elderly men it is often gouty, most commonly affecting the left testicle.

The disease is usually of a very chronic character. In some instances, however, it ceases spontaneously, after having lasted for weeks or months.

Treatment.—When the neuralgia is dependent upon constitutional causes the treatment is extremely unsatisfactory. The administration of tonics, such as iron, zinc, or quinine, the local application of sedatives, as of atropine ointment or the tincture of aconite, may be of service. In other cases, cold bathing or douching will be beneficial ; and, in all, keeping the part supported with a suspensory bandage will be advantageous. When it is due to gout the patient must be treated for that condition. In the event of there being any local irritation, that should be removed : thus, I have known the disease to

cease after the excision of external piles ; and when it is connected with varicocele, proper measures must be adopted for the relief of that affection.

The application of glycerine and belladonna or of a mixture of equal parts of chloral and camphor may give relief.

In extreme cases, Astley Cooper recommended castration ; but such a proceeding is altogether unjustifiable in a disease that is either constitutional or dependent on local causes which are readily removable.

ACUTE INFLAMMATION OF THE TESTIS.

Acute Inflammation of the Testicle may be seated in the body of the organ, constituting *Orchitis*, or the epididymis alone may be affected, constituting *Epididymitis*. But although the inflammation may remain limited to one or other of these structures, in the large majority of cases both are eventually involved.

Causes.—By far the most common cause of acute inflammation of the testicle is direct extension from the urethra. This variety, in which the epididymis is always primarily affected, is met with in gonorrhœa (p. 1169), and as the result of irritation set up in the canal by the passage of instruments or the lodgment of calculi. To the same class probably belong the cases in which an attack of epididymitis occurs as a complication of chronic inflammation or hypertrophy of the prostate, especially in gouty subjects. Inflammation, affecting chiefly the body, may occur as the result of an injury, such as a squeeze, blow, or severe strain. Orchitis may also occur as a sequela of certain acute infective diseases ; of these mumps is by far the most important, but amongst others in which the same complication has been observed may be mentioned typhoid fever and smallpox. Apart from the epididymitis which is met with in gouty subjects, probably as the result of urethral or prostatic inflammation, the existence of a true gouty orchitis in which the body of the testicle is affected seems undoubted. Orchitis has also been met with in association with other manifestations of acute rheumatism, but, as Jacobson remarks, before a diagnosis of “rheumatic orchitis” is made, not only must any urethral or other cause be excluded, but care must be taken to distinguish neuralgic pains in the epididymis or testis, to which gouty and rheumatic subjects are especially liable, from a supposed inflammation of the testicle.

The **Symptoms** necessarily vary, not only according as the disease is of an acute or subacute character, but as it primarily affects the body of the testis or the epididymis. When it commences in the latter structure it is the globus minor that is commonly first affected ; it becomes swollen, hard, and tender. The inflammation may be confined throughout to this part ; but most frequently it invades the whole of the organ, which becomes uniformly enlarged and somewhat ovoid ; it is frequently accompanied by a good deal of effusion into the tunica vaginalis, constituting the *Acute Hydrocele* of Velpeau. As the inflammation subsides, the different characters presented by the enlargement of the two constituents of the organ again become apparent. The swelling is therefore due partly to general enlargement of the organ, but in some cases to inflammatory effusion into the tunica vaginalis.

The pain is always very severe, with much tenderness and a sensation of weight, and commonly extends up the cord into the groin and loin. It is generally greatest when the body of the testis is affected, owing probably to the enveloping fibrous tunic preventing the expansion of the organ. Hence it is often spasmodic and paroxysmal, extending up the course of the cord. There are usually considerable swelling and redness of the scrotum, with turgescence of the scrotal veins, and a congested state of the cord, with sharp pyrexia, nausea, and perhaps occasional vomiting.

As the disease subsides, the body of the testis first resumes its normal character and shape, the epididymis often continuing hardened and enlarged for a considerable period. In fact, the induration that forms in the epididymis may be permanent, implicating the whole or a portion of its convolutions.

Gosselin has shown that this induration of the epididymis following inflammation frequently causes complete obstruction of the canal, and if occurring on both sides, produces sterility. In 19 such cases he found spermatozoa absent from the semen, and the patients consequently incapable of procreation, although the appearance of the testes and of their secretion was scarcely altered, and the virile powers of the patients remained unimpaired. Curling also mentions several such cases, and points out the necessity of continuing the treatment of epididymitis until the last trace of induration has disappeared. At a later period treatment is almost useless.

Subacute Orchitis usually comes on with the same symptoms, though in a less marked form than in the acute variety. The swelling, however, is considerable, though of a softer kind. Should it become chronic, the testis often remains permanently enlarged and hardened, assuming an oval shape, being smooth, heavy, and uniformly expanded, with a sensation of weight, dragging, and severe pain, and a good deal of tenderness on pressure. This form of orchitis occasionally occurs in old people.

Orchitis may occur idiopathically, without any assignable cause in the way of external injury or local irritation in the urethra or prostate. This form of the disease is most common in middle-aged men, and more especially in those who are gouty. In fact, the disease is in all probability one of the many local forms of gouty inflammation. It is not very acute but lingering, liable to recurrence, and to be followed either by hydrocele or chronic induration of the epididymis.

Atrophy of the Testis as a consequence of Inflammation is more liable to follow the orchitis of mumps in young men above the age of puberty than any other inflammatory affection of the organ. It is remarkable how rapid and how complete the wasting of the testis will be in these cases. A few weeks after the subsidence of the inflammation the testis may be found to form a small soft mass not larger than a filbert.

Atrophy of the testis may sometimes gradually ensue also as a result of chronic epididymitis, and the consequent induration of this structure. Strangulation of the vascular supply to the testis occurs, and the whole organ at last wastes so as to leave nothing but a small hardened mass in the scrotum.

Treatment of Acute Orchitis.—The patient should be kept in bed with the testis raised on a small pillow between the thighs, and hot fomentations diligently applied. At the same time the swollen gland may be painted with a mixture of equal parts of glycerine and extract of belladonna. This treat-

ment will usually be found to give the patient relief; but if the case be seen very early, before much swelling has taken place, the application of cold by means of Leiter's tubes (Vol. I., p. 214) or Otis's coil may sometimes cut the inflammation short and give immediate relief. Local blood-letting is often of great service when there is much pain. It is best carried out by puncturing the veins of the scrotum—a far better method than applying leeches, the bites of which are apt to become irritated. This little operation may be very effectually done by directing the patient to stand up, and to foment the scrotum for a few minutes with a hot sponge, so as to distend the veins: these may then be punctured at various points with a fine lancet, and the parts well fomented, so as to encourage the flow of blood. In this way six or eight ounces may be taken in the course of a few minutes; when enough has escaped, the further flow may be arrested by laying the patient down and elevating the part.

If there be much effusion into the tunica vaginalis, constituting a hydrocele, relief may be afforded by tapping. Puncture of the testis itself, which has been recommended, is a needless and dangerous proceeding. I have known of a case in which it was followed by abscess in the gland, ending in its complete destruction.

The *Constitutional Treatment* during the acute stage consists in the administration of salines and antimony, with hyoscyamus in full doses, so as to give an aperient, a diaphoretic, and a sedative together; when this begins to act, great relief is usually afforded.

As the inflammation subsides, the treatment must be changed. When there is merely swelling and hardness left, with but little pain or tenderness, the testis may advantageously be strapped, so as to give good support and to promote absorption of plastic matter. Fricke of Hamburg has strongly recommended strapping in the acute stage; but I cannot say that I have ever seen any advantage derived from it at this period of the disease, though I have many times seen it tried; it has usually appeared to me to increase, sometimes very considerably, the pain in the part, and the general uneasiness.

In **Subacute Orchitis** much benefit is usually derived from a short course of Dover's powder and calomel, with early strapping of the testis. When the organ has become enlarged and indurated, as the result of chronic inflammation, it may advantageously be strapped either with simple plaster, or with one composed of equal parts of the emplastrum ammoniaci cum hydrargyro and soap-plaster; mercury in small doses, more especially the perchloride, being continued for some length of time, until the inflammatory products are absorbed and the hardness disappears.

In **Strapping a Testicle**, the scrotum should be shaved, and then drawn tightly upwards on the affected side. The Surgeon should next pass a long strip of plaster, an inch broad, above the enlarged testicle and round the corresponding side of the scrotum, so as to isolate it. Another strip is now passed from behind, in a longitudinal direction, over the lower end of the testis, and upwards upon the anterior part of the scrotum; and then, by a succession of horizontal and vertical strips, neatly overlapping and drawn tightly, the organ is completely enveloped and compressed. To be of any service, the strapping must be tightly and evenly applied; but at the same time care must be taken not to strangulate the scrotum by drawing down the upper strips of plaster too forcibly. In a case of syphilitic disease of the

testis, in which I was obliged to have recourse to castration, the whole of the side of the scrotum had sloughed away, leaving the testis exposed and fungating, in consequence of the tight strapping which had been employed before the case came into my hands.

After the swelling has subsided, the patient must wear a suspensory bandage for some months.

The *Induration about the Epididymis*, which usually remains after epididymitis, must be treated by prolonged counter-irritation with tincture of iodine, or by the application of the iodide of lead or iodine ointment. So long as any induration is left it is doubtful whether the secretion is able to find its way through the thickened epididymis.

Abscess of the Testicle as the result of orchitis is rare, but is less exceptional after some forms of the disease than others. Gonorrhœal epididymitis is followed by suppuration only in extremely rare instances. Marmaduke Sheild, who has recently investigated this subject, has collected a considerable number of cases in which suppuration has followed the passage of instruments. Thus, abscess of the testicle has been known to follow catheterization, and also lithotomy and lithotrity. Traumatic orchitis rarely suppurates. With regard to the inflammation of the testicle which follows specific fevers, Terrillon and Monod state that orchitis after typhoid more frequently ends in suppuration than any other variety, whereas Sheild was unable to find a single recorded case in which abscess of the testicle had occurred after mumps. Wilks and Moxon mention four cases in which they found abscess of the epididymis in pyæmia. Simple abscess of the testicle must be carefully distinguished from those due to tuberculous or syphilitic disease, and also from suppuration in the cavity of the tunica vaginalis.

In true abscess of the testicle the pus forms under the tunica albuginea, adhesion takes place between the testis and the scrotum, the fibrous coat gives way, and the pus gets vent externally through the integuments. Into the aperture that necessarily results a portion of the secreting tissue of the gland sometimes projects, and, becoming inflamed, forms a red, granular, and fungous mass, protruding through and overlapping the edges of the aperture. The *treatment* consists in making an incision as soon as the presence of pus is suspected; if a fungus testis forms, it must be treated as described at p. 1252.

Inflammation and Abscess of the Cord.—In some cases the inflammation of the testis may extend, or the disease may, from the first, be limited to the areolar tissue of the cord, giving rise to tumefaction, with a good deal of pain and tenderness, and eventually abscess, accompanied by the usual signs of suppuration. The *Treatment* of such a case must be conducted on ordinary principles, early discharge for the pus being secured.

Chronic Orchitis of a persistent character constitutes a distinct disease of the testis, so closely allied to some forms of tumour of this organ in its character and pathology, that it will be more convenient to consider it with the Solid Enlargements of the Gland (p. 1251).

HYDROCELE.

By **Hydrocele** is meant an accumulation of serous fluid, formed in connexion with the testis or cord. In the most common form the fluid occupies

the sac of the tunica vaginalis; but in other instances it forms distinct cysts either in connexion with the testis or upon the cord. It will be convenient to describe hydrocele of the testis and hydrocele of the cord separately.

HYDROCELE OF THE TESTIS.—1. **Hydrocele of the Tunica Vaginalis, or Vaginal Hydrocele,** is the ordinary form of the disease. It may occur as the result of acute orchitis, the inflammation of the testis causing the effusion of a quantity of fluid into its serous investment (p. 1234). This, however, is not the kind of hydrocele that is commonly met with; the fluid so poured out as the result of active inflammation usually becoming absorbed as the parts recover their normal condition. The true or primary hydrocele occurs as a chronic disease, without any signs of inflammation of the testicle, or, at most, with but slight tenderness of that organ. It is most frequently met with in individuals about the middle period of life, commonly without any evident exciting cause, either constitutional or local. It is very common in men who have lived long in warm climates, and Fayer considers it in some cases to have a malarial origin. Hydrocele is also very frequently seen in infants when but a few days old, and may very possibly be present at the time of birth.

The **Symptoms** of hydrocele are tolerably evident. The disease begins with a degree of swelling and weight about the testis; the swelling may at first be soft, but after a while becomes hard and tense; or it may be so from the commencement. There is no impulse in it when the patient coughs. Whatever its original condition, the tumour soon becomes oval or pyriform in shape, being narrowed above, rounded and broad below; it is smooth and uniformly tense and hard; it usually fluctuates, but may have merely a semi-elastic feel. It reaches upwards along the cord towards the external abdominal ring, which, however, is rarely invaded by it.

Fig. 948.—Double Hydrocele, extending through the external abdominal ring and simulating hernia.

and the cord is usually distinctly to be felt above the upper limit of the tumour. Most commonly the size varies from that of a goose's egg to a small cocoa-nut; but sometimes it may attain a considerably greater magnitude than this, and will then cause much inconvenience, as it reaches up close to the external ring, and drags over the penis, causing that organ to be buried in it, so as to interfere with micturition. Gibbon, the historian, had an enormous hydrocele, which was tapped by Cline, who drew off six quarts of fluid.

The most characteristic sign of hydrocele is its translucency. This may always be detected by the Surgeon grasping the posterior part of the tumour with one hand, so as to put the integuments of the fore part on the stretch, then placing the edge of the other hand along the most prominent part of the swelling, and having a lighted candle held close behind. Another very simple and efficient method of determining the translucency is by putting the end of a stethoscope against the tumour, and looking down the tube against the light. If the walls of the sac be thick, or the fluid dark, the transmission

of light through it may not be perceived unless the examination be conducted in a darkened room, or it may even become completely opaque. It must not be forgotten that in infants a hernia may be translucent on account of the thinness of the structures at that age.

We have already seen that the ordinary hydrocele of the tunica vaginalis may vary as to size : it may also differ as to shape ; in some cases being globular, in others constricted in the middle, or of an hour-glass shape (Fig. 943).

The quantity of liquid varies considerably ; there are usually from six to twelve or twenty ounces, but I have known a hydrocele to contain more than one hundred and twenty ounces. The fluid is generally clear and limpid, and of a straw colour. The specific gravity is from 1020 to 1024. It contains albumen in large quantities, but not quite equal in amount to that in pure blood serum. Fibrinogen is abundantly present, but the fibrin-ferment is wanting, consequently the fluid is not spontaneously coagulable. Clotting can, however, be at once determined by the addition of a little blood serum containing white corpuscles. In very large and old hydroceles the fluid may become of a dark-brownish or chocolate hue, owing to the admixture of disintegrated blood ; and it will then be found to contain flakes of cholesterine. The sac is usually thin ; but in some old cases it becomes thick and dense, lined by a kind of false membrane, and divided by septa or bands, occasionally to such an extent as almost to separate it into distinct compartments. When the sac is thick, and the fluid opaque and turbid, there may be considerable difficulty in detecting the translucency.

The testis is often somewhat enlarged, especially about the epididymis, and frequently slightly tender, more particularly in the early stages of the complaint. It is almost invariably situated in the posterior part of the sac (Fig. 944), but may sometimes be found towards its anterior part. When this is the case, the epididymis will be found turned towards the front, owing to the organ being retroverted. If the hydrocele is of any size and tense, the testicle is lost in it. Its situation can then be recognized by the characteristic pain elicited by pressing on it, and by the opacity of the tumour at that point.

Two uncommon varieties of hydrocele of the tunica vaginalis need short mention.

In the so-called **Congenital Hydrocele**, the funicular portion of the processus vaginalis having remained unobliterated, the sac of the hydrocele is in communication with the peritoneal cavity, and the fluid occupies the same position as the intestine does in a so-called congenital hernia. It differs from an ordinary vaginal hydrocele only in the fact that by raising the tumour and gently squeezing it the fluid can be gradually made to flow back into the general peritoneal cavity.

The name **Infantile Hydrocele** has been applied to a hydrocele of the tunica vaginalis in which the funicular process has been obliterated only at the internal abdominal ring and remains patent below. The hydrocele has therefore a narrow prolongation above which occupies the inguinal canal. The extension of swelling into the inguinal canal and the consequent existence of a slight impulse on coughing render this variety of hydrocele more easily mistaken for hernia than the ordinary form ; it is, however, distinguished by its translucency, irreducibility, dulness on percussion, and distinct fluctuation.

The *Coverings* of a hydrocele are the same as those of the testis. Besides the integument, prolongations from the intercolumnar, cremasteric, and transversalis fasciæ may be traced over the surface of the swelling (Fig. 945).

The **Treatment** of hydrocele is *Palliative* and *Curative*. By the *Palliative* treatment the Surgeon seeks simply to relieve the patient of the annoyance caused by the bulk or weight of the tumour; but the *Curative* has for its object the permanent removal of the disease.

The **Palliative Treatment** consists in the use of a suspensory bandage and cooling lotion, or in tapping with a fine trochar. These simple means, however, will sometimes succeed in effecting a radical cure. Thus, in infants, it will happen that the application of evaporating lotions or mild counter-irritants may remove the effused fluid; and indeed it is seldom that any other plan of treatment than this is required in young children. A useful lotion for

Fig. 944.—Hydrocele of the Tunica Vaginalis laid open.

Fig. 945.—Dissection of a Hydrocele, showing its coverings.

the purpose consists of one composed of 3j of chloride of ammonium, 3j of spirits of wine, and 3viij of water; or tincture of iodine may be used. If there be a communication with the peritoneum, a truss should be applied over the inguinal canal. In adults it occasionally happens that simple tapping of the tumour has effected a cure. Many years ago a gentleman from Cuba consulted me for a small hydrocele which had been forming for several months; I tapped it with a fine trochar, and drew off about five ounces of fluid. This was followed by a radical cure. This case bears out a remark made by Brodie, that the few instances in which he had known simple tapping to produce a radical cure occurred in West Indians. I have, however, several times seen hydroceles disappear after having been tapped a few times, without any other treatment, in persons who had never been in hot climates. This simple operation is not, however, altogether free from danger; I have known an old man die from inflammatory œdema of the scrotum after having been

tapped, and tetanus also has followed this operation. After tapping, it usually happens that the hydrocele slowly forms again, attaining its former bulk at the end of about three months. Occasionally it will be found that the hydrocele returns more and more slowly after each tapping; so that, by repeating this simple process at intervals of three, then six, then twelve months, the disease will finally disappear. I have several times seen this occur, chiefly in old men. When a congenital hydrocele has been tapped, the sac soon fills again by drainage into it from the peritoneum; and, indeed, in such a case the fluid of an ascites has been drawn off by tapping the tunica vaginalis.

In tapping a hydrocele a few precautions are necessary, the principal being to avoid puncturing one of the scrotal veins, or injuring the testis. In the majority of cases the testis is situated at the back of the tumour, and is consequently altogether out of the way of the trochar. Its situation should, however, always be determined before the operation. This may be done by pressing with the finger firmly on different points of the sac in succession. The patient will usually be able at once to tell when the testicle is pressed upon by the peculiar "testicular sensation." The seat of the gland may be

Fig. 946.—Tapping a Hydrocele: *a*, Introduction of Trochar: *b*, Position of Cannula.

further determined by the want of translucency at the spot at which it is situated.

The operation is then performed as follows:—1. The trochar should be well washed in carbolic acid lotion (1 in 20). 2. The patient should be made to lie down or sit on a chair, lest he become faint. 3. The Surgeon, then grasping the hydrocele, draws the scrotum back so as to make the coverings on the front of the tumour as thin and smooth as possible. 4. He then selects a spot a little below the middle of the tumour where no vein is visible, and there taps the hydrocele. 5. The trochar must be held with its handle in the palm of the hand, and the index finger must be firmly pressed against the side about three quarters of an inch from its point to prevent its accidentally slipping in more deeply than is intended. It should not be thrust in with a sudden plunge—which is always painful and startling to the patient—but should be steadily pushed forwards, the tumour at the same time being pressed against its point. In this way the operation is almost painless, especially if care is taken to avoid blood-vessels and their accompanying nerves. The trochar is to be pushed in directly backwards (Fig. 946, *a*), but as soon as the trochar is withdrawn the cannula should be inclined obliquely upwards, so as to avoid the chance of pressure against the testis (Fig. 946, *b*). 6. When all the fluid has escaped, the cannula is slowly withdrawn, the edges of the small puncture are pressed together and covered with a little cotton-wool and collodion. A

suspensory bandage should then be put on, and rest enforced for a few hours. The fluid sometimes escapes with a pulsatory movement, apparently communicated by the arteries of the cord. If the testicle have been found in front, the hydrocele should be tapped at the side or behind.

Before using the trochar, it is well to see that the cannula fits closely round the neck of the trochar; and, above all, that the instrument has not become rusty by having been carelessly put aside after use on a previous occasion.

The means adopted in the **Curative Treatment** of hydrocele are very various, but may be grouped in three classes:—1. The injection of irritating fluids into the cavity; 2. Drainage; and 3. Partial excision of the sac.

In order that the radical cure, in whichever way undertaken, should be safe and efficient, it is necessary, in the first instance, that the disease should have been allowed to attain a chronic condition, more particularly if the hydrocele have been of rapid growth. In order to prevent its attaining too large a size, it will be well to adopt palliative tapping once or twice before attempting the radical cure. Care must also be taken to remove all inflammation and tenderness about the testis before having recourse to this mode of treatment. If attention be not paid to this, recurrence of the hydrocele will probably ensue.

The treatment by **Injection** is that which is commonly employed. It consists in tapping the tumour in the usual way, and then throwing a sufficient quantity of stimulating fluid into the tunica vaginalis through the cannula to excite a moderate degree of inflammation in it. Port-wine, or a solution of the sulphate of zinc of the strength of $\mathfrak{z}\text{i}$ to $\mathfrak{z}\text{xij}$, was formerly employed, but their use has been entirely abandoned since the introduction of iodine and carbolic acid for the purpose.

Injection of Iodine.—The injection of tincture of iodine, originally introduced by Sir J. R. Martin, whilst practising at Calcutta, is commonly regarded as a more certain and safe mode of treatment than any other. Many Surgeons prefer the liquor iodi to the tincture, believing it to be more certain in its effect. The operation is performed as follows: The hydrocele is tapped in the usual way and all the fluid withdrawn. If the patient dreads the pain, one drachm of a 5 per cent. solution of cocaine may be injected through the cannula and allowed a few minutes to render the part anæsthetic. The amount of the tincture of iodine injected should vary from two drachms to half an ounce, according to the size of the hydrocele. It is injected with a glass syringe, which must fit the cannula. After injection the Surgeon should rub the scrotum gently over the testis, so as to diffuse the injection equally throughout the sac. One half the quantity thrown in should then be allowed to escape, the cannula should be removed, and the puncture closed with a piece of strapping or wool and collodion. The cannula used for this purpose should be made of platinum and not of silver, which is apt to become corroded and made brittle by the iodine. A good deal of inflammation, with fresh effusion into the sac, will generally be set up, usually accompanied by subacute inflammation of the testicle. The patient should therefore keep in the recumbent position for a few days with the testicle raised. In favourable cases the effusion slowly and completely disappears, but for several weeks at least a suspender should be worn.

Useful as the iodine injection is, it sometimes fails in producing a radical cure of the hydrocele. This is sometimes due to the injection failing to bring

about sufficient inflammation. In other cases, the fluid effused as the result of the operation, instead of slowly disappearing, remains imperfectly or altogether unabsorbed. If the walls of the hydrocele are much thickened, injection may fail, as the cavity cannot collapse. In successful cases the result may sometimes be due to complete obliteration of the cavity of the tunica vaginalis by adhesions; but this is not necessarily so, and examination of the parts after death, in cases previously cured by injection, has sometimes shown a complete absence of adhesions.

The proportion of cases in which the iodine injection fails to bring about a radical cure of the hydrocele is variously estimated by different Surgeons. Thus, Martin stated that in India the failures scarcely amount to 1 per cent.; Velpeau calculated them at 3 per cent. I am not aware that any statistics of this mode of treatment in this country have been collected; but the general opinion of Surgeons would appear to be decidedly in its favour, as being the safest plan of treatment that has yet been introduced. In this opinion I fully concur: yet it is by no means improbable that the success of the iodine injection in this country would prove to be not quite so great as is generally believed. I have seen a considerable number of cases of simple hydrocele of the tunica vaginalis, both in hospital and in private practice, in which a radical cure had not been effected, although recourse had been had to the iodine injection by some of the most careful and skilful Surgeons of the day, as well as by myself. It is especially apt to fail in men advanced in years. In them there is either not sufficient inflammation excited, or if it be, the fluid that is as a consequence effused into the tunica vaginalis is not re-absorbed.

Injection of Carbolic Acid.—The use of carbolic acid, instead of iodine, as an injection for hydrocele, has been recommended by Levis of Philadelphia. The advantages claimed for carbolic acid over iodine are that it is more certain and less painful, and also that it produces a more rapid cure with less risk of complications.

Levis recommends that a drachm of pure carbolic acid be liquefied with 5 or 10 per cent. of glycerine. This is injected through the cannula, by which the fluid has been withdrawn, by means of a large hypodermic syringe. Or the Surgeon may follow Jacobson's suggestion to introduce the needle of an exploring syringe into the hydrocele, then to tap the hydrocele in the ordinary way, and after withdrawing the cannula, to screw the syringe on to the needle which is already in position and inject the liquefied carbolic acid. It cannot yet be considered proved that recurrence is less common after carbolic acid than iodine injections. The danger of carbolic acid poisoning seems to be extremely small.

Incision and Drainage.—The simple method of introducing a good-sized drainage-tube into the hydrocele and applying an antiseptic dressing has been found frequently to fail to effect a radical cure, the sac refilling after the tube was removed.

Free incision was, therefore, recommended by Volkmann. In his operation the sac is incised along its anterior aspect and the fluid evacuated and the cavity washed out with carbolic acid lotion (1 in 20); the tunica vaginalis is then attached to the skin by a few points of suture and the parts dressed antiseptically. The operation is not followed by orchitis, and the wound heals in about two weeks. The results have been very satisfactory, but relapses have occurred even after this.

Partial Excision of the Tunica Vaginalis, as recommended by Von Bergmann, must be regarded as the most certain method of treatment, and is available in cases in which from the thickness of the sac-wall injection is unlikely to be successful, or in which it has failed. The operation consists in freely exposing and opening the distended tunica vaginalis, separating the parietal layer from its coverings, and cutting it away at a short distance from the testicle. The edges of the divided tunica vaginalis are sutured to those of the skin.

Kocher and Juillard, however, advise that the sac should not be so extensively removed. They expose the tunica vaginalis and separate it from the superficial coverings of the testicle, great care being taken not to injure the vas deferens or vessels which may be spread out on the sac. All bleeding being arrested, the sac is opened and as much cut away as will leave a sufficient covering for the testicle. The edges of the sac are then united by catgut sutures, and finally the wound in the skin is united in the same way. Kocher recommends no drainage. Juillard drains the external wound. If all goes well no inflammation of the testicle or the sac follows, and the patient is well in eight days.

In hydrocele of children and infants **Acupuncture** will often be found to effect a cure. The scrotum having been put upon the stretch, the hydrocele is punctured at two or three points with a large darning-needle, introduced slowly by being rotated between the finger and thumb. From the punctures thus made the serum slowly escapes into the cellular tissue of the scrotum, whence in two or three days it is absorbed.

This mode of treatment will be found the safest and most effectual in the hydroceles of young children in whom it would be extremely dangerous to attempt a cure by injection of iodine. It may always be safely employed if the application of the lotion before mentioned fails to cure the disease.

It is not always prudent to have recourse to the radical cure in the treatment of hydrocele. In persons advanced in years, or of feeble and unhealthy constitution, the inflammation excited in the tunica vaginalis by any of the means just described may run on to such an extent as to give rise to inflammatory oedema, and even sloughing of the scrotum, with great danger to life. In these subjects it is much safer and usually sufficient to temporize with the hydrocele, and only to tap as occasion arises from the increasing size of the swelling.

Encysted Hydrocele of the Epididymis.—In this variety of the disease the fluid does not lie in the tunica vaginalis, but is contained in a cyst which projects from the surface of the epididymis.

Curling pointed out the fact, that small pedunculated cysts about the size of currants, and composed of a fine serous membrane, lined with tessellated epithelium, are very frequently found beneath the visceral tunica vaginalis covering the epididymis. They are delicate in structure, contain a clear limpid fluid, and are very liable to rupture. They are met with at all ages after puberty. According to Gosselin, after the age of forty they occurred in at least two-thirds of the testes examined to ascertain their presence. Such cysts as these may remain stationary, of small size, undiscernible during life; they may rupture into the tunica vaginalis; or they may enlarge and become developed into tumours of considerable size.

Testicular structures are present in the neighbourhood of the epididy-

mis, which may possibly be connected with the origin of these cysts : 1. The *Vas aberrans*, a remnant of the Wolffian duct, which forms a branched convoluted tube leading from the commencement of the vas deferens and extending a short distance up the cord ; 2. The *Organ of Giralès*, a relic of the Wolffian body, which comprises a few small convoluted tubes lined with columnar epithelium, situated immediately above the head of the epididymis ; and 3. The *Hydatids of Morgagni*, a relic of the Müllerian duct, which persists as the small pedunculated cysts above mentioned.

The fluid of these cysts possesses the remarkable characteristic, discovered by Liston, of containing spermatozoa (Fig. 947). Though spermatozoa do not always exist in this fluid, yet they are usually met with, sometimes in small quantities, at others so abundantly as to give it a turbid or opalescent appearance. This admixture of spermatozoa with the clear fluid of the cyst is probably due, as pointed out by Curling, to the accidental rupture of a seminal duct into an already existing cyst. Spermatozoa have also, but very rarely, been found in the fluid of an ordinary hydrocele of the tunica vaginalis ; and then probably their presence was due to the rupture of one of these cysts into the tunica vaginalis. Hence their presence in the fluid of hydrocele may in most cases be considered as characteristic of the encysted variety of the disease.

Fig. 947.—Spermatozoa from Encysted Hydrocele.

The *Signs* of encysted hydrocele of the epididymis differ in some respects from those presented by hydrocele of the tunica vaginalis. The tumour is smaller, more irregular in shape, and does not envelop the testis completely, but is situated behind and above it, in connexion with the epididymis.

The *Diagnosis* from ordinary hydrocele of the tunica vaginalis may be made by observing : 1. That the testis is below and in front, and not covered in by the encysted form of the disease ; 2. That the tumour is more globular or irregular, and less pyriform ; 3. When tapped, the fluid will usually be found to be opalescent.

Treatment.—In many cases, when the cyst is small, no treatment is necessary, and in others the swelling reappears so slowly after simple tapping that this alone is sufficient. Injection with strong tincture of iodine or with carbolic acid may bring about a cure, but the treatment does not seem so frequently successful in this as in the last form of hydrocele. If injection fail an incision should be made, and the cyst-wall either partially excised, or, if possible, completely enucleated.

Encysted Hydrocele of the Body of the Testis.—This name has been applied to cysts, usually small in size, which are very rarely met with in connexion with the body of the testis, where they lie between the tunica vaginalis and the tunica albuginea. In Astley Cooper's work a multilocular cyst of considerable size in this position is figured, but such a condition is exceedingly rare, and as a rule these cysts are of no practical importance.

HYDROCELE OF THE SPERMATIC CORD.—This occurs in two forms, the Encysted and the Diffused.

Encysted Hydrocele of the Cord.—This disease is characterized by the presence of a round or oval tumour, situated on the cord, below or within the inguinal canal. It is smooth, elastic, and, if of sufficient size, may show semi-transparency on examination by transmitted light. It can be pushed up into the abdomen, unless the testicle be drawn firmly down so as to put the cord on the stretch, when the cyst becomes fixed. It receives no impulse on coughing, and does not alter in size on being steadily compressed. Occasionally more than one cyst may be met with. It appears to be due, in most cases, to imperfect closure at one or more points of the funicular portion of the processus vaginalis, and to distension by fluid of the unclosed portions. In some instances in which the cyst lies at the lower end of the cord, it is possible that it arises as a cystic growth from the vas aberrans or the organ of Giralde's. These tumours may occur at all ages, but are met with chiefly in the young, and are not unfrequent amongst children. The fluid of a hydrocele of the cord is lighter in colour than that of one of the tunica vaginalis.

The *Treatment* of these cysts is best conducted by dissecting them out. If simply punctured they speedily fill again; injection of iodine is uncertain, and may give rise to troublesome inflammation. In dissecting them out care must be taken not to injure the constituents of the cord. If they rupture, and the whole wall cannot be got away, recurrence is very likely to occur.

The name *funicular hydrocele* is sometimes used for a rare condition in which the funicular process remains open, but is shut off below from the tunica vaginalis. A reducible swelling forms in front of the cord from accumulation of fluid in the open process.

Diffused Hydrocele of the Cord consists in the infiltration of the spermatic cord with serous fluid, contained in fairly distinct spaces, and giving rise to an oval or oblong irregular circumscribed tumour, extending below and into the inguinal canal. The *Treatment* consists in the application of blisters, or of counter-irritant plasters. Should the disease prove very troublesome, an incision might be made into the swelling, so as to let out the fluid and allow the cysts to become consolidated.

HÆMATOCELE.

By **Hæmatocele** is meant an accumulation of blood in connexion with the testicle or spermatic cord. In the large majority of cases the blood is effused into the cavity of the tunica vaginalis.

Hæmatocele of the Tunica Vaginalis is of two kinds, traumatic and spontaneous. The *Traumatic* is by far the more common form, usually arising from a blow on or a squeeze of the testis, by which one of the veins ramifying on the surface of the gland is ruptured, and blood is poured into the tunica vaginalis. It may arise also in tapping a hydrocele, from the point of the trochar being pushed too directly backwards and puncturing the testis, or wounding a vessel in the cord, or occasionally from a blow upon a hydrocele. *Spontaneous Hæmatocele* is a disease of rare occurrence, arising apparently from the rupture of an enlarged spermatic vein into the tunica vaginalis. It attains a larger size, and is altogether a more formidable affection, than the traumatic hæmatocele.

Characters.—In whatever way occurring, a hæmatocele slowly but gradually increases until it attains about the size of a duck's egg, or even that

of a cocoa-nut. It is seldom that it becomes larger than this ; but cases are recorded in which the tumour has attained an enormous magnitude. I once operated on a case in which a spontaneous hæmatocele had existed for six years ; it was as large as a melon, and contained, besides about a quart of dark thin blood, a handful of partially decolorized and tough fibrin, the greater portion of which was firmly adherent to the inside of the greatly thickened tunica vaginalis in filamentary and laminated masses, with here and there nodules interspersed. The whole of the interior of the tunica vaginalis closely resembled an aneurismal sac.

The fluid contained in the hæmatocele, when the disease is recent, consists of pure blood. The blood so effused will continue fluid for years ; but at last it may decompose and set up fatal inflammatory mischief ; in some rare instances the tumour becomes partly solidified by the deposit of masses of fibrin lining the interior of the tunica vaginalis, which are sometimes decolorized and arranged as in the case just referred to and in one recorded by Bowman. When the hæmatocele is of old standing, changes take place both in the effused blood and in the sac. The blood becomes at first dark and treacly. As chemical changes advance further it becomes converted into a dirty-brownish fluid, full of shreds of partly decolorized fibrin and crystals of cholesterine. The tunica vaginalis becomes thickened and indurated, and may undergo calcification. This change I found in a patient whose disorganized testis I removed for a hæmatocele of nearly forty years' standing.

The **Symptoms** are generally sufficiently obvious. The occurrence of the tumour subsequently to a blow, strain, or injury, its gradual increase in size, its heavy but semi-elastic or obscurely fluctuating feel, and the absence of translucency, form the most important signs. Its shape is somewhat uncertain. When recent it may have the pyriform shape of a hydrocele, but an old hæmatocele is always more or less oval or rounded in form and smooth on the surface, and thus comes closely to resemble a solid tumour. Except in very old cases, in which atrophy of the testicle from pressure has occurred, the peculiar "testicular sensation" will be perceived by the patient if the gland is pressed upon.

Diagnosis.—Hæmatocele may be mistaken for hydrocele, hernia, and other scrotal swellings. The mode of distinguishing it will be described at the end of this chapter, with the diagnosis of scrotal tumours in general. It is most frequently confounded with solid tumours of the testicle ; and upon this fact is founded the excellent rule of practice never to remove a doubtful tumour of the testis without first ascertaining, by an incision into its substance, that it is not a hæmatocele.

Treatment.—When the effusion of blood is only moderate in amount, and of quite recent occurrence, further hæmorrhage may be prevented by keeping the patient lying flat on his back with the scrotum raised on a small pillow, and an ice bag or evaporating lotion applied. If the blood shows no signs of undergoing absorption, the Surgeon may evacuate it with a trochar and cannula while it is still fluid. Every care must be taken to avoid setting up suppuration by the use of an imperfectly cleaned instrument. In a case under my care, although the hæmatocele had existed for three years, a complete cure followed the operation of tapping. Such simple treatment as this, however, cannot be depended upon, and it usually becomes necessary to lay open the

sac. This should be done very freely, the altered blood clot and fibrinous deposit being thoroughly removed from the sac. The operation can generally be completed by partially excising the sac wall and suturing its divided edges to those of the skin. The incision should be loosely plugged with a strip of gauze, and an antiseptic dressing applied. The remaining cavity is allowed to granulate from the bottom and thus become obliterated. If the tumour were of very large size, and the tunica vaginalis much thickened, hardened, and parchment-like, with adherent and laminated fibrin, castration might possibly be required. In the instance to which I have already referred, and which is represented in Fig. 948, this was rendered necessary in consequence of these conditions, and was successfully done.

Hæmatocoele of the Spermatic Cord has been observed by Pott, Curling, Bowman, and others; it is a rare disease, and usually occurs in the form of a tumour of considerable size, suddenly arising after a strain or some violent exertion, giving rise to rupture of a varicose spermatic vein. It

commences in the inguinal canal, and thence extends downwards along the course of the cord, through the abdominal ring into the scrotum; but it does not surround or implicate the testis, which can be felt free and movable at its lowest part. On incising such a tumour as this, a quantity of blood, partly fluid and partly coagulated, has been found, sometimes contained in a cavity occasioned by the laceration and separation of the tissues of the cord and scrotum. The most remarkable case of this kind on record is one related by Bowman, in which the tumour, after existing for ten years, had attained so enormous a size, that it reached to the patella, and was so heavy as to require both hands and a considerable effort to raise it from

Fig. 948.—Hæmatocoele with thickened Tunica Vaginalis and adherent Fibrin.

its bed. In this case, death appears to have resulted from decomposition of the contents of the tumour.

Diagnosis.—In its early stages, hæmatocoele of the cord would run considerable risk of being confounded with an *inguinal hernia*. The more diffused character of the swelling, however, its irregular feel, its semi-fluctuating sensation, and the impossibility of reduction, might enable the diagnosis to be made (p. 866.) Hæmatocoele of the cord may always be distinguished from an accumulation of blood in the tunica vaginalis, by the testicle not being implicated in the former case, but surrounded by the fluid in the latter.

The **Treatment** of this disease must in the earlier stages be of a palliative kind, consisting in rest, support of the tumour, and the application of evaporating lotions. Care should be taken not to incise it at this period, lest the loss of blood from the ruptured vein, after the evacuation of the contents of the tumour, become uncontrollable. In one instance I have known fatal consequences from this cause ensue in half an hour after making an incision into the tumour and turning out the coagula. When, however, the disease has reached a chronic stage, and is no longer increasing, it may be incised, and its contents being turned out, the cavity may be allowed to granulate.

VARICOCELE.

Varix, or Enlargement of the Spermatic Veins, is a disease that is commonly met with from the age of puberty to about the thirtieth year, seldom commencing later than this. It usually occurs in feeble individuals having the scrotum lax and pendulous; and in some cases appears to have been brought on by venereal excesses.

The spermatic veins passing from the testicle and epididymis form a considerable plexus of small vessels in the cord, known as the *pampiniform plexus*. In the inguinal canal the branches join into two or three veins, and these again into a single vessel which accompanies the spermatic artery beneath the peritoneum on the psoas muscle and opens on the right side into the vena cava, and on the left into the renal vein. The effect of this arrangement is that the lower part of the veins is subject to considerable tension from the weight of the long column of blood.

In varicocele the veins undergo changes similar to those already described in varices of the lower limb; they become dilated and thickened, except where thin-walled pouches form in the walls, and are very tortuous. When cut across the open mouths of the vessels stand open like that of an artery.

The veins of the left side are much more frequently affected than those of the right side; and never, I believe, are the right veins affected without those of the left side participating in the disease. In these cases of double varicocele, the left side is almost invariably the more seriously affected; but I have seen exceptions to this in one or two instances.

Various theories have been advanced in explanation of this peculiar liability of the left side to be affected. The theory that there is an obstacle at the mouth of the left vein, due to its pouring its contents into the renal vein at right angles to the flow of blood through that vessel into the vena cava, is probably altogether erroneous. Possibly the pressure of a loaded sigmoid flexure on the left spermatic vein may in some instances serve as a partial explanation. It does not appear that any constant difference exists in the arrangement of the valves on the two sides; a valve is usually present at the termination of each vein; this is not unfrequently absent on the left side, but, according to Rivington, a valve will then generally be found in the renal vein close to the entrance of the spermatic. W. G. Spencer, who believes that varicocele is due to a persistence and subsequent enlargement of foetal veins, which usually disappear, finds that at an early period the veins of the left spermatic cord are much more numerous than those of the right.

Symptoms.—The symptoms of varicocele consist of a tumour of pyramidal shape, having a soft knotted or knobbed feel, owing to the irregularly swollen and convoluted condition of the veins, with its base upon the testis and the apex stretching up to the external ring. The swelling increases when the patient stands up, if he take a deep inspiration, cough, or make any violent exertion. Its size varies from slight fulness of the veins to a large mass, several inches in circumference at the base. When the patient lies down, it goes up to a certain extent, but immediately returns to its former magnitude when he stands up. It is attended by a sensation of weight and sometimes of pain of a neuralgic character, which is occasionally very acute in the scrotum, the groins, and the loins, more particularly when the tumour is unsupported. This pain is greatly increased on the patient walking or riding; so that in

some cases he is almost debarred from taking exercise, and is prevented from following any active occupation. Debility of the generative organs, with a tendency to seminal emissions and much mental depression, frequently accompanies varicocele. Although the testicle of the affected side often feels rather smaller and softer than its fellow, atrophy as a result of varicocele is extremely rare. Rupture of one of the dilated veins may occur from external injury, giving rise to an enormous extravasation of blood into the areolar tissue of the scrotum. Of this Pott relates a case. I have known the accident to be attended with fatal consequences. A man who "had been romping with his wife" received a blow on a varicocele, when an enormous extravasation of blood rapidly formed in the scrotum and the cord, for which he was admitted into the Hospital. The tumour was incised, and large masses of coagula were turned out. The patient shortly after, in the absence of assistance, suddenly became faint and died of venous hæmorrhage. The bleeding was found to have proceeded from a ruptured spermatic vein.

Diagnosis.—The diagnosis of varicocele is always sufficiently easy; its peculiar convoluted feel, its broad base and narrow apex, the manner in which it goes up when the patient lies down, and returns again when he stands up, are sufficient to distinguish it from all other scrotal tumours. From *Inguinal hernia* the disease may be distinguished by attention to the test described at p. 868.

The Treatment of varicocele must be conducted with reference to the severity of the symptoms occasioned by it, and to the extent of the disease. When, as is usually the case, it gives rise to but slight inconvenience, palliative treatment is sufficient; but if, as occasionally happens, the disease be a source of actual suffering, or tend to the induction of generative debility, with much mental disquietude or hypochondriasis, then the Surgeon may feel disposed to endeavour to cure the varicocele radically.

The Palliative Treatment of varicocele consists in improving the condition of the general health by the use of tonics, improving the tone of the part by cold douches and sea-bathing, and supporting the scrotum in a well-made suspensory bandage.

The Radical Cure of Varicocele consists in the obliteration of the enlarged veins, on the same principle that guides us in the management of varix in other situations.

The circumstances for which operation may be practised are as follows:—

1. When the existence of a varicocele disqualifies the sufferer from admission into the public services. One of the cases in which I have effected a radical cure was that of a man in the prime of life, who, wishing to enlist in the Marines, was refused solely on the ground of his having a small varicocele. This I cured by operation, and the man afterwards entered the service.

2. In some cases, the presence of a varicocele of inordinate size causes a distressing sense of weight and pain in the loins and groins, and often inability to stand or walk for any length of time. Here, when the patient is in continual discomfort, or more or less prevented from pursuing his ordinary avocations, it is perfectly justifiable to resort to operation.

3. Cases not uncommonly occur where the pressure of the enlarged veins on the spermatic nerve produces repeated attacks of spermatorrhœa. These cases are, however, more frequently met with out of hospitals, than in individuals of the class who apply to such institutions for relief. In fact,

Young men of the more highly educated classes are very subject to varicocele, especially those who habitually lead a sedentary and studious life, as, for instance, young clergymen and lawyers. In these persons a peculiarly hypochondriacal state is brought on by the tendency of the mind to dwell on the condition of the genital organs, and the patient is constantly fidgeting about the local and tangible disease he observes in them.

Since the introduction of the antiseptic treatment of wounds the various methods which were at one time adopted for the subcutaneous ligature or strangulation of the enlarged veins have been superseded by the more certain plan of ligature and excision. The operation is thus performed: An incision, from one and a half to two inches in length, is made over the spermatic cord, commencing above just below the external abdominal ring. The skin and superficial fascia are then dissected carefully through until the cord is exposed. An assistant then feels for the vas deferens, and holding this back with the thumb and index finger of the two hands he makes the mass of veins project prominently into the wound. These are readily isolated *en masse* from the vas behind, and secured above and below with silk. The part of the veins which lies between the ligatures is then excised, and by tying the two ligatures together, as suggested by W. H. Bennett, the cord is correspondingly shortened.

Another method consists in isolating the individual veins and ligaturing and excising them separately. This necessarily increases the length of the operation, and in separating the veins it may be difficult to avoid wounding them. It has, however, been claimed as an advantage of this method that the spermatic artery is not occluded, whereas, when the veins are tied *en masse*, it seems certain that the spermatic artery is also included. It does not, however, appear that there is any risk of atrophy of the testicle as the result of this. The small wound may safely be completely sutured without drainage, and the first dressing may be left unchanged for a week, at the end of which time the wound will usually be found to have united by the first intention.

SOLID ENLARGEMENTS OF THE TESTIS.

All solid enlargements of the testicle were formerly classed together under the term **Sarcocoele**; and when they were conjoined with fluid accumulations in the tunica vaginalis, they were termed **Hydro-sarcocoele**. There seems, however, no advantage in the continued use of these terms. Solid enlargements of the testicle may be divided into *Chronic Orchitis*, *Syphilitic* and *Tuberculous Disease*, and the true *Tumours*.

Chronic Orchitis.—In this a chronic enlargement of the testis results from inflammatory mischief in the organ not arising from syphilis or tubercle. Such cases are undoubtedly rare. Our increased knowledge of both tubercle and syphilis has taught us that the great majority of cases formerly classed as simple orchitis are really due to one of these two causes. Still, excluding all such cases, a residue is left to which the name of simple orchitis may be applied.

Causes.—Chronic orchitis may be a consequence of acute inflammation from any cause. It also arises from blows or squeezes in old people. Most commonly it is associated with some disease of the urinary organs, such as stricture or chronic enlargement of the prostate. In other cases it may be associated with rheumatism or gout.

Symptoms.—The testicle feels hard, smooth, and solid, though perhaps slightly elastic at points; it is ovoid in shape, and usually about as large as a duck's egg. It is heavy and but slightly painful, and, except in very old cases, the testicular sensation is present. The cord is usually somewhat thickened and, as well as the groin, is the seat of pain of a dragging character. The tunica vaginalis occasionally contains serous fluid lying in front of and obscuring the testis. The scrotum is always healthy, and almost invariably one testicle only is affected.

Occasionally simple chronic inflammation may terminate in **Suppuration**. In these circumstances, a part of the indurated testicle softens and becomes prominent, the skin becomes red, shining and thinned, and adhesions form between it and the gland beneath. At last the abscess bursts, and through the aperture a fungus (**hernia testis**, or **benign fungus of the testicle**)

speedily protrudes, which grows sometimes slowly, sometimes rapidly, perhaps attaining a very considerable size (Fig. 949). As the fungus increases the organ appears to atrophy, but in reality is pressed out of the scrotum and merges into the fungus. This fungus is not a new growth, but is composed of the tubules of the testis and inflammatory products. It is in the form of a pale reddish-yellow granular mass. If small and firm it may become very chronic; but if large, rapidly growing, and loose-textured, it speedily destroys the secreting structure of the testis, leaving nothing but a thickened epididymis and a contracted and shrunken tunica albuginea. In other cases no fungus appears, but a fistulous track may be left, leading to an imperfectly

Fig. 949.—Hernia Testis.

drained cavity surrounded by indurated tissue, and this may remain unhealed for months or even years. Occasionally, instead of bursting, the abscess may become surrounded by dense fibroid tissue and remain stationary, and this dense wall has been known to calcify. Although the occasional occurrence of abscess of the testicle as the result of simple chronic orchitis seems probable, it may be regarded as practically certain that many cases have been in reality tuberculous.

Structure.—On making a section of a testicle affected with simple chronic inflammation, the tunica vaginalis will be found to be more or less adherent, and perhaps separated from the tunica albuginea in parts by small collections of fluid. The tunica albuginea is thickened, often presenting on its external surface a series of firm, glistening layers. The septa of the testis are seen to be thickened, rendering the whole organ hard and firm, and giving it a bluish-grey appearance. The microscope shows that the chronic inflammation chiefly affects the intertubular tissue, but in many cases this is accompanied by catarrhal overgrowth of the epithelium.

Prognosis.—Simple chronic orchitis usually terminates in recovery, but the organ may be left somewhat enlarged and indurated, or in other cases it may undergo atrophy as the inflammatory products become absorbed.

Treatment.—Strapping and the administration of an alterative course of perchloride of mercury may be tried. If the organ do not diminish in size, or

if it be a source of much inconvenience to the patient, it must be removed. If accompanied by hydrocele the tunica vaginalis must be tapped, but on no account should injection of iodine be resorted to. If abscesses form, they must be opened. When a fungus has protruded, means must be taken to repress or remove this, lest it go on to complete destruction of the testis. If it be of small size, the best plan will be to sprinkle it with iodoform, and to strap it tightly down with a piece of lint and strapping. If it be larger, it may be shaved off, and the cut surface then dressed with some antiseptic application; care being taken during cicatrization to repress the granulations below the level of the surrounding integument by strapping and pressure. Syme recommended that the pressure should be effected by the integument of the part; an elliptical incision being made round the fungus and the edges of the opening in the skin through which it protrudes pared away, the scrotal integuments are freely separated by dissection from their subjacent connexions, and brought together over the protruding mass and secured by sutures. This operation I have practised with success. Should the fungus be of very large size, so as to include within itself the whole or greater part of the structure of the testis, it may not be possible to save any of that organ; and in these circumstances it is better to remove the whole gland; if left it could never be of any service, and would continue slowly to suppurate.

Tuberculous Disease of the Testicle, although occasionally met with in individuals apparently strong and healthy, usually occurs in those of a feeble or cachectic constitution, most frequently in early manhood, but occasionally in advanced life or childhood, and, although often associated with phthisis, it may occur without any evidence of tubercle in other organs. It is very common to find both glands affected, but the disease is usually more advanced in one than in the other. In some cases it arises apparently as a sequence of gonorrhoeal epididymitis, or there may be a history of some injury to the testicle. The disease almost invariably commences in the epididymis, which becomes swollen, indurated, and slightly tender. The globus minor is generally affected before the globus major. As the disease progresses, it spreads upwards along the vas deferens until it may reach the prostate and vesiculæ seminales, and forwards through the mediastinum testis into the body of the gland. In some rare cases, it is said to commence in the body of the gland. The progress of the disease is usually slow, but it may go on rapidly to almost complete destruction of the testis. In a well-marked case the following conditions will be found. The testicle is moderately enlarged, but on examination this enlargement will be found to be chiefly in the epididymis, which can be felt as an irregular, craggy, nodulated mass, half surrounding the body of the gland in the form of a crescent situated at its posterior aspect. In the hard mass, which often considerably exceeds the body

Fig. 950.—Tuberculous Disease of Testicle. The epididymis is completely converted into a caseous mass. The disease has invaded the upper end of the body, in which a few separate tubercles are also seen.

of the gland in bulk, spots of softening may be felt. The gland itself may seem soft and natural, or a nodule or two may be felt in its substance. The affection is not as a rule complicated by hydrocele, and in the earlier stages the scrotum is unaffected. The spermatic cord will usually present no general thickening, but the vas deferens is enlarged. Instead of feeling like a piece of whipcord between the fingers it may be as large as a quill. If the disease have extended to the vesiculæ seminales, these can be felt *per rectum* to be enlarged and hardened. There is little or no pain, and on squeezing the gland the ordinary sensation will be perceived by the patient except in a very advanced stage of the disease. As the disease advances, one of the craggy nodules softens, and the skin becomes adherent over it. This process is accompanied by more acute inflammation, usually causing marked increase of pain and tenderness. The adherent skin becomes red and shining, and finally gives way, and the tuberculous abscess discharges, leaving an unhealthy cavity yielding thin pus mixed with soft, shreddy, whitish-yellow sloughs. In some favourable cases the cavity may granulate and close completely, or leave merely a fistulous opening discharging small quantities of serous fluid. In most cases, however, the process of softening extends, other nodules break down, and a great part of the testicle may be destroyed. If an abscess should form in the body of the gland, a hernia or fungus testis may follow, as in simple chronic orchitis. Occasionally exuberant granulations may sprout out from the region of the epididymis, closely resembling the true fungus testis. The general health suffers greatly, and in a large proportion of cases tuberculous disease of the lungs makes its appearance. Most commonly the opposite testicle also becomes affected. Death usually results from the disease of the lungs, but may occur from acute general tuberculosis with tuberculous meningitis. Occasionally the disease may extend to the urinary tract, and terminate fatally from tuberculous disease of the kidneys. In other cases the disease of the testis may occur after that of the kidney and prostate, forming merely a part of general genito-urinary tuberculosis.

In some cases of phthisis, in which the testicles enlarge, and yet give but little trouble, the whole organ, both body and epididymis, may be found converted into a uniform soft cheesy mass. A specimen of two such testicles, from a patient who died from disease of the lungs, is in the museum of University College. In cases of acute general tuberculosis, grey granulations have been found in the testicles.

Structure.—On making a section from before backwards through a typical specimen of tuberculous disease of the testicle, the following conditions will be found. The tunica vaginalis may be perfectly healthy, or may be here and there adherent to the tunica albuginea. The tunica albuginea will be normal in appearance, except in the immediate neighbourhood of the tuberculous growth, where it will be thickened. That part of the body of the gland nearest the surface may be perfectly healthy in appearance; there is no thickening of the septa, and the tubules can be teased out under water as in a healthy testicle. As we approach the mediastinum, the gland becomes studded with small hard nodules, not growing in the septa, but in the glandular substance of the testis. In their earliest stage these are merely hard semi-transparent granulations; but they soon show signs of undergoing fatty degeneration in the centre, so that the majority have the appearance of small bodies about the size of a millet-seed, having a yellow opaque centre, and a delicate greyish semi-trans-

parent growing margin. Still nearer the mediastinum these yellow spots coalesce, and form a solid cheesy substance, continuous with a still larger mass of the same kind, which represents the epididymis, and half surrounds the body of the gland in the shape of a crescent. In this larger mass patches of softening are found, forming the tuberculous abscesses above described, and these may extend into the body of the gland. On making transverse sections of the vas deferens, its walls will be seen to be thickened, and its centre filled up with a yellow cheesy material. If the disease be further advanced, the whole gland may be converted into a single cheesy mass, in which softening may be taking place at various parts.

The exact nature of the change that takes place in the production of the condition above described, has given rise to much difference of opinion; some authors maintaining that the primary change consists in an overgrowth of the epithelium of the tubuli seminiferi and epididymis, which afterwards

Fig. 951.—Tuberculous Testis. a. Tubuli seminiferi: b. Giant-cells (40 diam.).

undergoes fatty degeneration; and others asserting that the primary growth takes place between the tubules, and that the changes in the epithelium are secondary.

The accompanying drawing (Fig. 951) represents a section of one of the small outlying nodules in the body of the gland. It will be seen that the change consists in an accumulation of small round cells in a more or less perfect reticulate stroma between the tubules, separating them from each other. At the same time the walls of the tubules have undergone a change, being infiltrated with cells in the same way. The tubules also are choked with epithelium, which in some parts of the same testicle was found to be undergoing fatty degeneration. Towards the centre of the nodule the intertubular growth also becomes caseous. Scattered through the new growth are many large masses of protoplasm containing many nuclei, the tuberculous giant-cells. It is most probable, therefore, that the change commences in the vascular tissue between the tubuli seminiferi, and gives rise to secondary

epithelium; both the intertubular growth and the tubular epithelium afterwards undergoing fatty degeneration, and forming

Prognosis.—The prognosis of tuberculous disease of the testis is extremely of little if any avail, and the patient in the great majority of cases dies of later of disease of the lungs, from general acute tuberculosis, or of the disease to the bladder, prostate, and even to the bones. However, after the abscesses have burst, the cavities of the testicle remain withered, but free from active disease.

Treatment.—The more I see of this disease the more convinced I am that if the diseased organ is removed the better will be the patient's chance of life. The danger of infection of the system by a tuberculous testis is so great, that when once the diagnosis is made castration should not be delayed. In most cases the disease extends along the vas deferens beyond the reach of the knife, and will continue to progress in the vesiculæ seminales and prostate, even if the testis is removed. In patients who succumb early to tuberculous disease of the lungs, and in whom the disease is confined to the testis, and in which, by examining it, the urine must be examined for pus, and the prostate and vesiculæ seminales ascertained from the rectum, the treatment of course, be useless if the affection of the testicle is a general tuberculosis of the whole genito-urinary tract. Should the patient be fit to submit to the operation, or his health be so bad that its performance is inadvisable, the treatment must be conducted on general principles, especially the iodide of iron, with cod-liver oil. The means calculated to improve the health, must be steadily pursued. Local applications are of little avail. The abscesses must be opened. The cavity should be thoroughly scraped out with a curette, and filled with iodoform. Under this treatment it sometimes cures, but the cure is rarely permanent. If fungus form, it is of little use. The methods before described; if the body of the testis is affected, and the tubercle, no good could result.

Secondary Disease of the Testicle.—The testicle may be affected in the secondary stage of the acquired disease, and also as the result of syphilis. In the secondary stage of acquired syphilis one or both testicles are occasionally affected. In the later stages of the disease, and in the inherited form, the body of the testicle is enlarged, and, as in other viscera, the simple inflammatory and the tuberculous forms are met with.

Inflammatory Form, which has been accurately described by Virchow as a chronic inflammatory overgrowth of the tubuli seminiferi. The disease may uniformly or be limited to localized patches. If the whole gland is affected, it enlarges to perhaps more than double its natural size. The disease will be found to affect the body of the gland, the cord being little if any change; in fact, it may be so far contracted as to be scarcely recognizable. The cord is unaffected. The body of the gland feels hard, almost smooth, and the surface is smooth or perhaps slightly irregular. There is a dragging sensation in the groin due to the increased

weight of the testicle. There is little or no tenderness, and in the more advanced stages testicular sensation is absent. There is no tendency to softening or to the formation of abscess. The disease is almost always accompanied by hydrocele, but at the same time adhesions may exist at various parts between the parietal and visceral layers of the tunica vaginalis, dividing the fluid into two or more portions, or limiting it to a small part of the surface of the testicle. Most commonly only one testicle is affected, but both may be attacked. In the localized form the induration is limited to one or more portions of the gland, the remainder being soft and healthy.

Structure.—On making a section from before backwards, the following appearances are found : If hydrocele exist, the tunica vaginalis will be opaque and thickened, and probably adherent at various points to the surface of the testicle. If no hydrocele be present, the tunica vaginalis may be uniformly adherent. The tunica albuginea will always be found greatly and irregularly thickened, and from it proceed opaque white dense fibroid processes into the substance of the gland. These may in extreme cases be so abundant that no healthy gland substance can be seen between them ; in less severe cases,

2

Fig. 952.—Syphilitic Gummata of the Testis. a, b. Gummata cut across : c. Section of Globus minor : and d. Cord.

patches of healthy tubular substance are found at various parts of the organ. A process of cicatricial contraction taking place in these fibroid processes may lead to a dimpling of the surface of the organ. The microscope shows that the change is due to an inflammatory small round-celled growth, which afterwards undergoes a development into a dense fibroid tissue, situated in the connective tissue between the tubuli seminiferi (Fig. 952). The new growth separates and presses on the tubules, and may cause their destruction in large areas.

The **Gummatous Form** is an aggravation of that just described, and presents the same symptoms, with the addition of those caused by the presence of the gummata. These form hard craggy nodules on the surface of the gland, the irregularities so produced being much greater than those arising from simple fibroid induration. The gummata have little tendency to soften, and discharge externally ; yet in rare cases they may do so.

Structure.—On making a section of a gland in this condition, more or less of the fibroid induration, above described, will always be found combined with thickening of the tunics of the testicle. The gummata vary in size, from a pea to a hazel-nut. They are of an opaque yellow colour, irregular

shape, and dense leathery hardness. They may be tolerably sharply circumscribed to the naked eye, but are usually surrounded by a zone of fibrous induration of an opaque white colour. The microscope shows around them the same small-celled growth above described, situated between the tubules. The new growth is vascular in the most recent parts. In the older parts the changes described in the chapter on Syphilis (Vol. I., p. 1133) may be seen in their walls, causing their gradual obliteration. Nearer the centre the tubules are found to be pressed upon and destroyed, and the cells of the new growth commence to undergo degeneration; until, in the yellow part of the gumma, nothing but granular *débris* is to be recognized. The gummata may be distinguished from tubercle by their greater toughness and more opaque yellow colour. Tubercle is rarely limited to the body of the testis; gummata, on the other hand, are rarely limited to the epididymis.

Prognosis.—If the disease be recognized and treated early, complete recovery

Fig. 958.—Syphilitic Testis. a. Tubuli Seminiferi; b. A part of the round-celled growth beginning to undergo fatty degeneration (180 diam.).

may confidently be hoped for; although relapses are of frequent occurrence. In the more advanced stages, the prognosis is not so hopeful, for, although under proper treatment the new growth may be absorbed, the gland will remain shrunken, puckered, and indurated. This is only what would be expected; for the tubuli seminiferi, as above stated, become more or less extensively destroyed by the pressure of the new growth in the later stages of the disease.

The **Treatment** is that recommended in Chapter XXXVI. for constitutional syphilis. Locally, the hydrocele may be tapped (but on no account injected), and pressure may be applied, by strapping over some mercurial ointment.

Diagnosis of the Simple, Tuberculous, and Syphilitic Enlargements.—The diagnosis of these affections is in some cases easy, in others very difficult. Whatever the form of disease may be, if it be complicated by hydrocele, this may first be tapped in order that the gland may be accurately examined. The hydrocele in these cases may not be translucent, as the tunica vaginalis is often thickened. It must be remembered that hydrocele is a very rare complication of carcinoma, or of adenoma; it is rare with tuberculous disease; less rare with simple chronic orchitis, and very common with syphilitic disease.

From hæmatocele and tumours, the diagnosis may be made by attention to the rules laid down on p. 1266. It having been determined that the swelling is due to one of the three above-mentioned causes, it remains to ascertain which it is. This may be done by attention to the following points: The cord is often thickened and tender in simple chronic orchitis; in tuberculous disease, the vas deferens alone is affected, being frequently considerably enlarged; in syphilis the cord is perfectly healthy. In simple chronic orchitis, the epididymis may be swollen, but the chief enlargement is in the body; in tuberculous disease, the epididymis is almost always the starting-point of the disease, and is enlarged more than the body; in syphilis, the body is first and almost exclusively affected. In chronic orchitis, the enlargement is usually uniform and smooth, and fluctuation is rarely present; in tubercle, the enlarged epididymis is craggy and nodular, and spots of softening may be felt; in syphilis, the body of the gland is greatly indurated, often nodulated, and softening is very rare. The testicle is usually painful and tender in chronic orchitis; in tubercle it is sometimes tender, seldom painful; in syphilis, it is almost invariably perfectly painless, and free from tenderness. The constitutional condition of the patient should also be carefully inquired into. Chronic orchitis usually arises as a sequence of injury, or perhaps gonorrhœa, in patients possibly strumous, gouty, or rheumatic; tuberculous disease occurs almost always in cachectic subjects, with a tuberculous history and a tendency to phthisis. The lungs should therefore be carefully examined. In syphilis, the ordinary symptoms of constitutional syphilis may be present, or a syphilitic history may be obtained. In tuberculous disease, the vesiculæ seminales may often be felt through the rectum to be enlarged, and nodules of tubercle may be felt in the prostate.

TUMOURS OF THE TESTIS.

SIMPLE TUMOURS.—**Adenoma**, or, as it has been called, *Cystic Sarcoma*, is the most common non-malignant tumour of the testicle.

Structure.—The essential feature of this tumour is the presence of cysts, varying in size from a cavity just visible to one as large as a walnut. Between these cysts is a varying amount of solid tissue. The whole tumour lies within the distended tunica albuginea, but will be found to possess a delicate capsule of its own, between which and the tunica albuginea is a delicate layer of a pale yellowish-brown colour, composed of the tubular substance of the testicle spread out over the mass of the growth. The attachment of the tumour is towards the mediastinum testis, and this suggests that the growth springs from the region of the rete testis, the cysts being believed to be derived from the obstructed and dilated tubes of that part of the gland.

Microscopic examination shows that the cysts are lined with an epithelium, sometimes small and cubical, sometimes flattened. The interstitial tissue is composed of young connective tissue in various degrees of development.

This is the typical structure of adenoma testis, but various modifications are met with. In the first place, the proportion of cysts to stroma varies greatly. The contents of the cysts may be clear and thin, or mucous and tinted, or stained with blood. More rarely they are filled with an atheromatous pulp. Occasionally some of the smaller cysts are filled with laminated epithelium, forming pearl-like bodies.

The stroma may be purely composed of spindle cells, or spindle and round cells mixed, or spindle cells with a good deal of fibrous tissue between them. Almost invariably cartilage is present. It is usually in tortuous columns,

which are clearly visible to the naked eye, and can be picked out of a thick section with a needle. It has been suggested that these columns of cartilage are lying in dilated lymphatics, but careful microscopic examination suggests rather that they are formed by chondrification of the embryonic matrix. The matrix in other cases may assume a myxomatous form, the intercellular substance being mucous in appearance and the cells stellate in form. In many cases the intercellular substance sprouts up into the cysts, forming intra-cystic growths still covered with epithelium. These tumours are usually simple and distinctly encapsuled, but in some cases they became malignant. This may occur from an exuberant growth of the embryonic tissue of the stroma, or, according to Rindfleisch, actual cancerous transformation may take place, the stroma assuming the form of a cancer stroma and the epithelium of the spaces taking on the active growth

of a true carcinoma. Many of these variations may occur in different parts of the same growth.

Symptoms.—These tumours are most common in young adults or middle-

Fig. 955.—Section of an Adenoma of the Testicle showing the cysts, the embryonic interstitial tissue and the columns of cartilage.

aged men, and are often attributed to a blow. They cause a steady increase in the size of the testicle, unaccompanied by pain or tenderness. Their growth is of varying rapidity, but they often take a year or more to attain

any considerable size. They are firm and elastic, and fluctuating points can not uncommonly be detected in them. The cord is unaffected till a late period unless they become malignant. The epididymis is early flattened out by the growth and cannot be recognized. If not removed they may attain a very great size, and at last the skin covering them may give way and the growth may fungate and bleed.

Diagnosis.—The tumour is distinguished from hydrocele by its want of

translucency, its more globular form and its weight. All doubt may be cleared up by an exploratory puncture.

Treatment.—The only treatment is early removal, always preceded by an incision into the mass to make sure that it is not a hæmatocele or a hydrocele.

Enchondroma of the Testicle.—Cartilage, as before stated, is almost always present in the adenoma of the testis. It may, however, appear alone, in larger or smaller nodules, or infiltrating the gland. It usually commences in the body, and may invade the epididymis. According to Cornil and Ranvier, whenever it reaches any considerable size it is no longer purely cartilaginous, but is mixed with sarcoma tissue and complicated with cysts, so that both clinically and pathologically it merges into the disease just described as cystic sarcoma.

Fibroma has been recorded, but is of extremely rare occurrence.

Dermoid Cysts are occasionally met with in the testicle, usually in the body of the gland, causing atrophy of the tubular substance by their pressure. They are of course congenital, but are of very slow growth, and may not be noticed till adult life. They usually contain turbid fluid or an atheromatous pulp, often mixed with hairs. In other cases they may lie outside the gland in contact with the epididymis. A case of this kind occurred in University College Hospital lately in which the cyst, which was about the size of the normal gland, lay in contact with the globus minor. It was dissected away without injuring the gland, and was probably a scrotal dermoid which had become adherent to the epididymis.

In other cases foetal remains may be found in the cyst. One of the most remarkable of these tumours that I have seen was under the care of the late

John Marshall. The diseased organ, which was ostrich's egg, and felt partly solid and partly fluid. to be composed of a large cyst filled with an oil which solidified on cooling. After removal it contained some foetal debris, and it was doubtful. The patient, who was about thirty years of age, had a tumour from early infancy.

MALIGNANT TUMOURS.—**Sarcoma** of the testis just described is not very common. It is cancer before removal, presenting the same structure, giving rise to a smooth elastic testicle. It is usually met with in young children.

Its microscopic structure varies. The most common variety, and often runs a course with large spindle cells intermixed. In rare cases tumours containing striated muscle cells have been found in the testicle. Tumours of the same structure met with in young children.

The *Treatment* consists in early removal. **Carcinoma of the Testicle** is the soft glandular variety.

Characters.—Cancer of the testis is found in the body of that organ primarily. The ordinary character of this affection; and the tumour is soft and pulpy. The mass on section is

malignant affections of the testis require local treatment, and the patient; in the operation be practised, the skin cleaned. The patient should be placed around the seat of the disease, and 1 in 20 carbolic lotion is applied to the testicle to be removed, and the cord, in order to make the incision extend from the external ring. If the operation is being performed, the cord has to be extended upwards, and the cord reached at as high a point as possible. In tuberculous cases, the cord is included between two curved forceps already indicated. By a division of the cord, whilst the skin is kept upon its scrotal attachments, and the cord must then be divided. In some cases the cord is divided in the first place, and divide the cord in the first place from the scrotum, as in this way a division of the cord constitutes the first step. Unless care be taken, it may retract. This accident is best prevented by more especially the cremasteric ligature above the point at which the ligature consists in transfixing the two halves separately with stout sutures, left long. The cord is next divided, and it is then allowed to retract, and ligatures are efficiently applied and the cord is retracted by traction. If no oozing takes place, the cord is drawn into view and the ends of the

are tied up the vessels separately in forceps, and a separate suture to each. The veins must be tied separately, requiring ligature are usually arteries of the vas. The spermatic artery of the vas deferens behind the vas, than simple transfixion, has been found to be more than when the nerves of the cord are not, however, found that much pain is caused, and in castration for malignant disease, the advantage that it allows the surgeon to do, would otherwise do, especially if the cord is not cut, and the inguinal canal opened. urs of the scrotum may, from a diagnostic
view, be divided into two distinct classes:—
educible; and 2, the Irreducible.

Reducible Tumours.—These are Hernia,
nital Hydrocele, Diffuse Hydrocele of the
, and Varicocele; in all of which the swelling
be made to disappear more or less completely
pressure and by the patient lying down; re-
appearing on the removal of the pressure, or on his assuming the erect
ature. The mode in which the tumour disappears tends greatly to
establish its diagnosis; though the general character of the swelling, and the
history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse
on coughing, &c. On reducing the tumour, it will be found that its return
into the abdomen is accompanied by a gurgling noise, and by the sudden slip
upwards of an evidently solid body. In the other reducible tumours, the

Fig. 957.—Carcinoma of the Testicle with Hydrocele of the Tunica Vaginalis and of the Cord.

OPERATION OF CASTRATION.

This operation may be required for the various non-malignant affections of the testicle that have resisted ordinary constitutional and local treatment, and have become sources of great annoyance and discomfort to the patient ; in the early forms of malignant disease, also, it may advantageously be practised. Before the operation the parts should be thoroughly shaved, the skin cleansed, and a carbolized towel applied for two or three hours. The patient should be lying on his back on a suitable table, and the parts around the seat of the incision should be covered with towels wrung out in 1 in 20 carbolic lotion. The Surgeon should stand on the same side as the testicle to be removed, and should grasp it at its posterior part with his left hand, in order to make the scrotum in front of it tense. The incision should extend from the external abdominal ring to the lower end of the scrotum. If the operation is being performed for malignant disease the incision will have to be extended upwards, in order that the inguinal canal may be opened and the cord reached at as high a level as possible. If the disease, as often occurs in tuberculous cases, has involved the skin, the affected part must be included between two curved incisions, meeting above and below at the points already indicated. By a few touches with a broad-bladed scalpel, whilst the skin is kept upon the stretch, the tumour is separated from its scrotal attachments, and left connected merely by the cord, which must then be divided. In some cases it will be found advantageous to expose and divide the cord in the first instance before dissecting out the tumour from the scrotum, as in this way a better command over it is obtained. The *division of the cord* constitutes the most important part of the operation, for, unless care be taken, it may retract into the inguinal canal and bleed freely. This accident is best prevented by separating the cord cleanly from the sheath—more especially the cremasteric fascia—and seizing it with clamp forceps above the point at which the ligature is to be applied. The simplest method of ligature consists in transfixing the cord with an aneurysm needle and tying the two halves separately with stout silk, the ends of which are for the present left long. The cord is next divided about half an inch below the ligatures, and it is then allowed to retract slightly, in order to make sure that the ligatures are efficiently applied and that bleeding is not being prevented merely by traction. If no oozing takes place from the stump it is drawn gently down into view and the ends of the ligatures cut off.

Another method consists in picking up the vessels separately in forcipressure forceps, and applying a fine ligature to each. The veins must be tied as well as the arteries. The arteries requiring ligature are usually the spermatic, the cremasteric, and the artery of the vas. The spermatic artery will be found in front, and the artery of the vas deferens behind. This method, which is far more tedious than simple transfixion, has been supposed to be followed by less pain than when the nerves of the cord are included in the ligature. I have not, however, found that much pain is complained of after the ligature *en masse*, and in castration for malignant disease this method certainly has the advantage that it allows the Surgeon to divide the cord at a higher level than he would otherwise do, especially if the incision be prolonged upwards and outwards, and the inguinal canal opened.

In castration for tuberculous disease it is better to separate the vas deferens

from the other constituents of the cord and to divide it separately. If it be found diseased it may be drawn down and a further piece removed in the hope of getting above the disease.

A large number of vessels usually require ligature in the scrotum. All bleeding from this source must be very thoroughly arrested, otherwise the loose tissues of the scrotum may become distended with extravasated blood and very troublesome suppuration may result. After the operation the wound must be accurately closed with sutures and a drainage-tube inserted at its lower end.

There is one danger that may occur in castration in children. It is that in young subjects the processus vaginalis testis may not be obliterated, and that thus the peritoneum may be opened up into the wound on dividing the cord. In one case I have known this condition lead to fatal peritonitis.

In some cases considerable induration and tenderness persist in the position of the stump of the divided cord, and occasionally the ligatures set up irritation, and may lead to a small abscess, which refuses to heal until the ligatures have come away. After castration for tuberculous disease a chronic abscess may form around the cord, probably as the result of the vas deferens having been diseased above the point of division.

GENERAL DIAGNOSIS OF SCROTAL TUMOURS.

The diagnosis of scrotal tumours is not only of considerable importance, but is often attended with very great difficulty; the more so, as they are frequently associated with one another, so that much tact and care are required to discriminate their true nature. Thus, it is not uncommon to find a hydrocele and a hernia; a hydrocele and a varicocele; or these affections co-existing with a solid tumour of the testicle. In other cases, again, as in Fig. 957, a carcinomatous tumour may co-exist with a hydrocele of the tunica vaginalis, and with an encysted hydrocele of the cord; and the different forms of hydrocele may occur together.

Tumours of the scrotum may, from a diagnostic point of view, be divided into two distinct classes:—1, the Reducible; and 2, the Irreducible.

1. **Reducible Tumours.**—These are Hernia, Congenital Hydrocele, Diffuse Hydrocele of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure and by the patient lying down; re-appearing on the removal of the pressure, or on his assuming the erect posture. The mode in which the tumour disappears tends greatly to establish its diagnosis; though the general character of the swelling, and the history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse on coughing, &c. On reducing the tumour, it will be found that its return into the abdomen is accompanied by a gurgling noise, and by the sudden slip upwards of an evidently solid body. In the other reducible tumours, the

Fig. 957.—Carcinoma of the Testicle with Hydroceles of the Tunica Vaginalis and of the Cord.

proliferation of the epithelium; both the intertubular growth and the proliferated epithelium afterwards undergoing fatty degeneration, and forming cheesy masses.

Prognosis.—The prognosis of tuberculous disease of the testis is extremely bad. Treatment is of little if any avail, and the patient in the great majority of cases dies sooner or later of disease of the lungs, from general acute tuberculosis or from extension of the disease to the bladder, prostate, and even to the kidneys. In some cases, however, after the abscesses have burst, the cavities may heal, and the testicle remain withered, but free from active disease.

Treatment.—The more I see of this disease the more convinced I am that the sooner the diseased organ is removed the better will be the patient's chance of prolongation of life. The danger of infection of the system by acute tuberculosis from a tuberculous testis is so great, that when once the diagnosis has been made castration should not be delayed. In most cases however the operation is at best calculated to give the patient only temporary relief, as the disease usually extends along the vas deferens beyond the reach of the knife, and will continue to progress in the vesiculæ seminales and prostate, unless the patient succumb early to tuberculous disease of the lungs or brain. Before undertaking it, the urine must be examined for pus, and the state of the prostate and vesiculæ seminales ascertained from the rectum, as the operation would, of course, be useless if the affection of the testicle were merely a part of tuberculosis of the whole genito-urinary tract. Should the patient decline to submit to the operation, or his health be so bad that its performance is not advisable, the treatment must be conducted on general principles: alteratives, tonics, especially the iodide of iron, with cod-liver oil, and general hygienic means calculated to improve the health, must be steadily persevered with. Local applications are of little avail. The abscesses must be opened when they form. The cavity should be thoroughly scraped out with a sharp spoon and dressed with iodoform. Under this treatment it sometimes heals rapidly, but the cure is rarely permanent. If fungus form, it is of little use to try to treat it by the methods before described; if the body of the testis be deeply infiltrated with tubercle, no good could result.

Syphilitic Disease of the Testicle.—The testicle may be affected in the secondary and tertiary stages of the acquired disease, and also as the result of inherited syphilis in infants. In the secondary stage of acquired syphilis one or both epididymises are occasionally affected. In the later stages of the acquired disease, and also in the inherited form, the body of the testicle is primarily affected, and, as in other viscera, the simple inflammatory and the gummatous varieties are met with.

The **Simple Inflammatory Form**, which has been accurately described by Virchow, consists essentially of a chronic inflammatory overgrowth of the connective tissue between the tubuli seminiferi. The disease may uniformly affect the whole gland or be limited to localized patches. If the whole gland be affected, the organ slowly enlarges to perhaps more than double its natural size. The enlargement will be found to affect the body of the gland, the epididymis undergoing but little if any change; in fact, it may be so far concealed by the thickening round it as to be scarcely recognizable. The cord and vas deferens are unaffected. The body of the gland feels hard, almost cartilaginous, and the surface is smooth or perhaps slightly irregular. There is no pain, except a dragging sensation in the groin due to the increased

weight of the testicle. There is little or no tenderness, and in the more advanced stages testicular sensation is absent. There is no tendency to softening or to the formation of abscess. The disease is almost always accompanied by hydrocele, but at the same time adhesions may exist at various parts between the parietal and visceral layers of the tunica vaginalis, dividing the fluid into two or more portions, or limiting it to a small part of the surface of the testicle. Most commonly only one testicle is affected, but both may be attacked. In the localized form the induration is limited to one or more portions of the gland, the remainder being soft and healthy.

Structure.—On making a section from before backwards, the following appearances are found : If hydrocele exist, the tunica vaginalis will be opaque and thickened, and probably adherent at various points to the surface of the testicle. If no hydrocele be present, the tunica vaginalis may be uniformly adherent. The tunica albuginea will always be found greatly and irregularly thickened, and from it proceed opaque white dense fibroid processes into the substance of the gland. These may in extreme cases be so abundant that no healthy gland substance can be seen between them ; in less severe cases,

2

Fig. 952.—Syphilitic Gummata of the Testis. a, b, Gummata cut across : c, Section of Globus minor : and d, Cord.

patches of healthy tubular substance are found at various parts of the organ. A process of cicatricial contraction taking place in these fibroid processes may lead to a dimpling of the surface of the organ. The microscope shows that the change is due to an inflammatory small round-celled growth, which afterwards undergoes a development into a dense fibroid tissue, situated in the connective tissue between the tubuli seminiferi (Fig. 952). The new growth separates and presses on the tubules, and may cause their destruction in large areas.

The **Gummatous Form** is an aggravation of that just described, and presents the same symptoms, with the addition of those caused by the presence of the gummata. These form hard craggy nodules on the surface of the gland, the irregularities so produced being much greater than those arising from simple fibroid induration. The gummata have little tendency to soften, and discharge externally ; yet in rare cases they may do so.

Structure.—On making a section of a gland in this condition, more or less of the fibroid induration, above described, will always be found combined with thickening of the tunics of the testicle. The gummata vary in size, from a pea to a hazel-nut. They are of an opaque yellow colour, irregular

shape, and dense leathery hardness. They may be tolerably sharply circumscribed to the naked eye, but are usually surrounded by a zone of fibrous induration of an opaque white colour. The microscope shows around them the same small-celled growth above described, situated between the tubules. The new growth is vascular in the most recent parts. In the older parts the changes described in the chapter on Syphilis (Vol. I., p. 1133) may be seen in their walls, causing their gradual obliteration. Nearer the centre the tubules are found to be pressed upon and destroyed, and the cells of the new growth commence to undergo degeneration; until, in the yellow part of the gumma, nothing but granular *débris* is to be recognized. The gummata may be distinguished from tubercle by their greater toughness and more opaque yellow colour. Tubercle is rarely limited to the body of the testis; gummata, on the other hand, are rarely limited to the epididymis.

Prognosis.—If the disease be recognized and treated early, complete recovery

Fig. 953.—Syphilitic Testis. a. Tubuli Seminiferi. b. A part of the round-celled growth beginning to undergo fatty degeneration (180 diam.).

may confidently be hoped for; although relapses are of frequent occurrence. In the more advanced stages, the prognosis is not so hopeful, for, although under proper treatment the new growth may be absorbed, the gland will remain shrunken, puckered, and indurated. This is only what would be expected; for the tubuli seminiferi, as above stated, become more or less extensively destroyed by the pressure of the new growth in the later stages of the disease.

The **Treatment** is that recommended in Chapter XXXVI. for constitutional syphilis. Locally, the hydrocele may be tapped (but on no account injected), and pressure may be applied, by strapping over some mercurial ointment.

Diagnosis of the Simple, Tuberculous, and Syphilitic Enlargements.—The diagnosis of these affections is in some cases easy, in others very difficult. Whatever the form of disease may be, if it be complicated by hydrocele, this may first be tapped in order that the gland may be accurately examined. The hydrocele in these cases may not be translucent, as the tunica vaginalis is often thickened. It must be remembered that hydrocele is a very rare complication of carcinoma, or of adenoma; it is rare with tuberculous disease; rare with simple chronic orchitis, and very common with syphilitic disease.

From hæmatocele and tumours, the diagnosis may be made by attention to the rules laid down on p. 1266. It having been determined that the swelling is due to one of the three above-mentioned causes, it remains to ascertain which it is. This may be done by attention to the following points: The cord is often thickened and tender in simple chronic orchitis; in tuberculous disease, the vas deferens alone is affected, being frequently considerably enlarged; in syphilis the cord is perfectly healthy. In simple chronic orchitis, the epididymis may be swollen, but the chief enlargement is in the body; in tuberculous disease, the epididymis is almost always the starting-point of the disease, and is enlarged more than the body; in syphilis, the body is first and almost exclusively affected. In chronic orchitis, the enlargement is usually uniform and smooth, and fluctuation is rarely present; in tubercle, the enlarged epididymis is craggy and nodular, and spots of softening may be felt; in syphilis, the body of the gland is greatly indurated, often nodulated, and softening is very rare. The testicle is usually painful and tender in chronic orchitis; in tubercle it is sometimes tender, seldom painful; in syphilis, it is almost invariably perfectly painless, and free from tenderness. The constitutional condition of the patient should also be carefully inquired into. Chronic orchitis usually arises as a sequence of injury, or perhaps gonorrhœa, in patients possibly strumous, gouty, or rheumatic; tuberculous disease occurs almost always in cachectic subjects, with a tuberculous history and a tendency to phthisis. The lungs should therefore be carefully examined. In syphilis, the ordinary symptoms of constitutional syphilis may be present, or a syphilitic history may be obtained. In tuberculous disease, the vesiculæ seminales may often be felt through the rectum to be enlarged, and nodules of tubercle may be felt in the prostate.

TUMOURS OF THE TESTIS.

SIMPLE TUMOURS.—**Adenoma**, or, as it has been called, *Cystic Sarcoma*, is the most common non-malignant tumour of the testicle.

Structure.—The essential feature of this tumour is the presence of cysts, varying in size from a cavity just visible to one as large as a walnut. Between these cysts is a varying amount of solid tissue. The whole tumour lies within the distended tunica albuginea, but will be found to possess a delicate capsule of its own, between which and the tunica albuginea is a delicate layer of a pale yellowish-brown colour, composed of the tubular substance of the testicle spread out over the mass of the growth. The attachment of the tumour is towards the mediastinum testis, and this suggests that the growth springs from the region of the rete testis, the cysts being believed to be derived from the obstructed and dilated tubes of that part of the gland.

Microscopic examination shows that the cysts are lined with an epithelium, sometimes small and cubical, sometimes flattened. The interstitial tissue is composed of young connective tissue in various degrees of development.

This is the typical structure of adenoma testis, but various modifications are met with. In the first place, the proportion of cysts to stroma varies greatly. The contents of the cysts may be clear and thin, or mucous and tinted, or stained with blood. More rarely they are filled with an atheromatous pulp. Occasionally some of the smaller cysts are filled with laminated epithelium, forming pearl-like bodies.

The stroma may be purely composed of spindle cells, or spindle and round cells mixed, or spindle cells with a good deal of fibrous tissue between them. Almost invariably cartilage is present. It is usually in tortuous columns

which are clearly visible to the naked eye, and can be picked out of a thick section with a needle. It has been suggested that these columns of cartilage are lying in dilated lymphatics, but careful microscopic examination suggests rather that they are formed by chondrification of the embryonic matrix. The matrix in other cases may assume a myxomatous form, the intercellular substance being mucous in appearance and the cells stellate in form. In many cases the intercellular substance sprouts up into the cysts, forming intra-cystic growths still covered with epithelium. These tumours are usually simple and distinctly encapsuled, but in some cases they become malignant. This may occur from an exuberant growth of the embryonic tissue of the stroma, or, according to Rindfleisch, actual cancerous transformation may take place, the stroma assuming the form of a cancer stroma and the epithelium of the spaces taking on the active growth

Fig. 954.—Adenoma of the Testicle. The external covering is the tunica vaginalis; the next layer is the tunica albuginea; the thin imperfect layer under this is the tubular substance of the testicle spread out over the true capsule of the tumour.

of a true carcinoma. Many of these variations may occur in different parts of the same growth.

Symptoms.—These tumours are most common in young adults or middle-

Fig. 955.—Section of an Adenoma of the Testicle showing the cysts, the embryonic interstitial tissue and the columns of cartilage.

aged men, and are often attributed to a blow. They cause a steady increase in the size of the testicle, unaccompanied by pain or tenderness. Their growth is of varying rapidity, but they often take a year or more to attain

any considerable size. They are firm and elastic, and fluctuating points can not uncommonly be detected in them. The cord is unaffected till a late period unless they become malignant. The epididymis is early flattened out by the growth and cannot be recognized. If not removed they may attain a very great size, and at last the skin covering them may give way and the growth may fungate and bleed.

Diagnosis.—The tumour is distinguished from hydrocele by its want of

Fig. 966.—Adenoma of the Testicle more highly magnified, showing the stroma composed of spindle cells and fibres, and the cyst lined with cubical epithelium and part of a column of cartilage.

translucency, its more globular form and its weight. All doubt may be cleared up by an exploratory puncture.

Treatment.—The only treatment is early removal, always preceded by an incision into the mass to make sure that it is not a hæmatocele or a hydrocele.

Enchondroma of the Testicle.—Cartilage, as before stated, is almost always present in the adenoma of the testis. It may, however, appear alone, in larger or smaller nodules, or infiltrating the gland. It usually commences in the body, and may invade the epididymis. According to Cornil and Ranvier, whenever it reaches any considerable size it is no longer purely cartilaginous, but is mixed with sarcoma tissue and complicated with cysts, so that both clinically and pathologically it merges into the disease just described as cystic sarcoma.

Fibroma has been recorded, but is of extremely rare occurrence.

Dermoid Cysts are occasionally met with in the testicle, usually in the body of the gland, causing atrophy of the tubular substance by their pressure. They are of course congenital, but are of very slow growth, and may not be noticed till adult life. They usually contain turbid fluid or an atheromatous pulp, often mixed with hairs. In other cases they may lie outside the gland in contact with the epididymis. A case of this kind occurred in University College Hospital lately in which the cyst, which was about the size of the normal gland, lay in contact with the globus minor. It was dissected away without injuring the gland, and was probably a scrotal dermoid which had become adherent to the epididymis.

In other cases foetal remains may be found in the cyst. One of the most remarkable of these tumours that I have seen was under the care of the late

John Marshall. The diseased organ, which was about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling. After removal Marshall found that the sac contained some foetal *débris*, and it was doubtless of an embryonic character. The patient, who was about thirty years of age, had been affected with the tumour from early infancy.

MALIGNANT TUMOURS.—**Sarcoma** of the testicle without the presence of the cysts just described is not very common. It is indistinguishable from cancer before removal, presenting the same rapid growth, and softness of structure, giving rise to a smooth elastic globular or oval enlargement of the testicle. It is usually met with in younger subjects than cancer, sometimes even in young children.

Its microscopic structure varies. Small round-celled sarcoma is by far the most common variety, and often runs a very malignant course. Myxo-sarcoma, with large spindle cells intermixed with it, has been described. In very rare cases tumours containing striated muscular fibres mixed with spindle cells have been found in the testicle. They exactly resemble the congenital tumours of the same structure met with in connexion with the kidney.

The *Treatment* consists in early removal of the gland by castration.

Carcinoma of the Testicle not unfrequently occurs, and is invariably of the soft glandular variety.

Characters.—Cancer of the testicle most commonly occurs in the first instance in the body of that organ, rarely, if ever, affecting the epididymis primarily. The ordinary characters of encephaloid are always well marked in this affection; and the tumour eventually fungates, becoming softened and pulpy. The mass on section is soft, pink in colour, with large yellow patches of fatty degeneration scattered through it. Its substance is often broken down in parts by hæmorrhage. It is impossible to distinguish it from a soft sarcoma without microscopic examination. The microscopic structure is that of a soft glandular carcinoma. The stroma is small in amount but extremely vascular, and encloses spaces of great size filled with large cells of irregular form.

A carcinoma of the testicle may rapidly attain a very considerable magnitude, becoming as large as a cocoa-nut in a few weeks or months. When of this size it is, of course, abundantly supplied with blood-vessels; consequently the spermatic artery and accompanying veins will be found a good deal dilated. The lymphatic glands in the neighbourhood speedily become enlarged, as may be ascertained by deep pressure in the flank. The inguinal glands do not in general become affected until the skin has become implicated by the process of the disease. It is then also that the cancerous cachexia rapidly develops itself.

The **Symptoms** of carcinoma of the testicle are usually somewhat obscure in the early stages, although they become clearly and distinctly developed as the disease progresses. It is most commonly met with after middle life. The patient first complains of some degree of dragging pain and weight in one of the testes, which on examination will be found to be indurated and enlarged, though preserving its normal shape. The enlargement continues until the testicle attains about the size and shape of a duck's egg, being somewhat tense and elastic, but smooth and heavy. As it increases in size, which it usually does with rapidity, it becomes rounded and somewhat doughy or pulpy

in parts, where, indeed, it may almost be semi-fluctuating, though in others it continues hard and knobbed. This alteration in feel is partly due to softening of the substance of the tumour, and partly to its making its way through the tunica albuginea. The scrotum is much distended, reddened, and purplish, and becomes covered by a network of tortuous veins; the cord may become somewhat enlarged, hard, and knotty. As the disease advances, the scrotum becomes adherent at some of the softened parts, ulceration takes place, and a fungus projects, which presents all the characteristic signs of fungus hæmatodes; it does not commonly happen, however, that the disease is allowed to go so far as this before removal. The pain is not very severe at first, but after a time assumes a lancinating character, extending up the cord and into the loins.

Treatment.—The only treatment of any avail in cancer of the testicle is the removal of the diseased organ. This operation is not performed so much with the view of curing the patient of his disease, which will probably return in the lymphatic glands or in some internal organ, as of affording temporary relief from the suffering and encumbrance of the enlarged testicle. It is therefore an operation of expediency, and should be done only in those cases in which the disease is limited to the testicle, the cord being free and the glands not evidently involved; so that, if recurrence take place, it may not be a very speedy one.

An **Undescended Testis** may become the seat of a tumour, just as it may be affected by inflammation. The combination of malposition of the organ and a tumour is necessarily rare. But its possible occurrence must be borne in mind by the Surgeon, as it may lead to the necessity of an operation for the removal of the diseased mass from the inguinal canal. Cases of this kind are recorded by Storks and J. M. Arnott. The tumour in the first case was as large as a cocoa-nut; in the second as a man's fist. Both were medullary. The operation consists in exposing the tumour by a free incision—if necessary, carried through the tendon of the external oblique—opening the tunica vaginalis, enucleating the mass, and tying with care the shortened spermatic cord, which would probably be the most difficult part of the operation. The possible co-existence of a congenital hernia must be remembered. But it is remarkable that peritonitis does not appear to be the chief danger of this operation. In neither of the cases above referred to did it occur, the patient dying of erysipelas in Arnott's case; of recurrent cancer, a year after the operation, in that of Storks.

SOLID TUMOURS OF THE SPERMATIC CORD.

Fatty Tumours are not very uncommon. They most commonly occur as small isolated masses near the inguinal ring. They grow slowly and are of no importance except from their resemblance to hernia. The tumour can be pushed through the external ring, but it has no impulse on coughing, nor is there the characteristic slip and gurgle of a hernia as it goes back. Large lipomata invading the scrotum as well as the cord have also been recorded.

Fibromata and Myxomata of the Cord have been recorded, but are merely pathological curiosities.

Sarcomata have also been met with in this region.

John Marshall. The diseased organ, which was about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling. After removal Marshall found that the sac contained some foetal *débris*, and it was doubtless of an embryonic character. The patient, who was about thirty years of age, had been affected with the tumour from early infancy.

MALIGNANT TUMOURS.—**Sarcoma** of the testicle without the presence of the cysts just described is not very common. It is indistinguishable from cancer before removal, presenting the same rapid growth, and softness of structure, giving rise to a smooth elastic globular or oval enlargement of the testicle. It is usually met with in younger subjects than cancer, sometimes even in young children.

Its microscopic structure varies. Small round-celled sarcoma is by far the most common variety, and often runs a very malignant course. Myxo-sarcoma with large spindle cells intermixed with it, has been described. In very rare cases tumours containing striated muscular fibres mixed with spindle cells have been found in the testicle. They exactly resemble the congenital tumours of the same structure met with in connexion with the kidney.

The *Treatment* consists in early removal of the gland by castration.

Carcinoma of the Testicle not unfrequently occurs, and is invariably of the soft glandular variety.

Characters.—Cancer of the testicle most commonly occurs in the first instance in the body of that organ, rarely, if ever, affecting the epididymis primarily. The ordinary characters of encephaloid are always well marked in this affection; and the tumour eventually fungates, becoming softened and pulpy. The mass on section is soft, pink in colour, with large yellow patches of fatty degeneration scattered through it. Its substance is often broken down in parts by hæmorrhage. It is impossible to distinguish it from a soft sarcoma without microscopic examination. The microscopic structure is that of a soft glandular carcinoma. The stroma is small in amount but extremely vascular, and encloses spaces of great size filled with large cells of irregular form.

A carcinoma of the testicle may rapidly attain a very considerable magnitude, becoming as large as a cocoa-nut in a few weeks or months. When of this size it is, of course, abundantly supplied with blood-vessels; consequently the spermatic artery and accompanying veins will be found a good deal dilated. The lymphatic glands in the neighbourhood speedily become enlarged, as may be ascertained by deep pressure in the flank. The inguinal glands do not in general become affected until the skin has become implicated by the process of the disease. It is then also that the cancerous cachexia rapidly develops itself.

The **Symptoms** of carcinoma of the testicle are usually somewhat obscure in the early stages, although they become clearly and distinctly developed as the disease progresses. It is most commonly met with after middle life. The patient first complains of some degree of dragging pain and weight in one of the testes, which on examination will be found to be indurated and enlarged, though preserving its normal shape. The enlargement continues until the testicle attains about the size and shape of a duck's egg, being somewhat tense and elastic, but smooth and heavy. As it increases in size, which it usually does with rapidity, it becomes rounded and somewhat doughy or pulpy

in parts, where, indeed, it may almost be semi-fluctuating, though in others it continues hard and knobbed. This alteration in feel is partly due to softening of the substance of the tumour, and partly to its making its way through the tunica albuginea. The scrotum is much distended, reddened, and purplish, and becomes covered by a network of tortuous veins; the cord may become somewhat enlarged, hard, and knotty. As the disease advances, the scrotum becomes adherent at some of the softened parts, ulceration takes place, and a fungus projects, which presents all the characteristic signs of fungus hæmatodes; it does not commonly happen, however, that the disease is allowed to go so far as this before removal. The pain is not very severe at first, but after a time assumes a lancinating character, extending up the cord and into the loins.

Treatment.—The only treatment of any avail in cancer of the testicle is the removal of the diseased organ. This operation is not performed so much with the view of curing the patient of his disease, which will probably return in the lymphatic glands or in some internal organ, as of affording temporary relief from the suffering and encumbrance of the enlarged testicle. It is therefore an operation of expediency, and should be done only in those cases in which the disease is limited to the testicle, the cord being free and the glands not evidently involved; so that, if recurrence take place, it may not be a very speedy one.

An **Undescended Testis** may become the seat of a tumour, just as it may be affected by inflammation. The combination of malposition of the organ and a tumour is necessarily rare. But its possible occurrence must be borne in mind by the Surgeon, as it may lead to the necessity of an operation for the removal of the diseased mass from the inguinal canal. Cases of this kind are recorded by Storks and J. M. Arnott. The tumour in the first case was as large as a cocoa-nut; in the second as a man's fist. Both were medullary. The operation consists in exposing the tumour by a free incision—if necessary, carried through the tendon of the external oblique—opening the tunica vaginalis, enucleating the mass, and tying with care the shortened spermatic cord, which would probably be the most difficult part of the operation. The possible co-existence of a congenital hernia must be remembered. But it is remarkable that peritonitis does not appear to be the chief danger of this operation. In neither of the cases above referred to did it occur, the patient dying of erysipelas in Arnott's case; of recurrent cancer, a year after the operation, in that of Storks.

SOLID TUMOURS OF THE SPERMATIC CORD.

Fatty Tumours are not very uncommon. They most commonly occur as small isolated masses near the inguinal ring. They grow slowly and are of no importance except from their resemblance to hernia. The tumour can be pushed through the external ring, but it has no impulse on coughing, nor is there the characteristic slip and gurgle of a hernia as it goes back. Large lipomata invading the scrotum as well as the cord have also been recorded.

Fibromata and Myxomata of the Cord have been recorded, but are merely pathological curiosities.

Sarcomata have also been met with in this region.

OPERATION OF CASTRATION.

This operation may be required for the various non-malignant affections of the testicle that have resisted ordinary constitutional and local treatment, and have become sources of great annoyance and discomfort to the patient ; in the early forms of malignant disease, also, it may advantageously be practised. Before the operation the parts should be thoroughly shaved, the skin cleansed and a carbolized towel applied for two or three hours. The patient should be lying on his back on a suitable table, and the parts around the seat of the incision should be covered with towels wrung out in 1 in 20 carbolic lotion. The Surgeon should stand on the same side as the testicle to be removed, and should grasp it at its posterior part with his left hand, in order to make the scrotum in front of it tense. The incision should extend from the external abdominal ring to the lower end of the scrotum. If the operation is being performed for malignant disease the incision will have to be extended upwards, in order that the inguinal canal may be opened and the cord reached at as high a level as possible. If the disease, as often occurs in tuberculous cases, has involved the skin, the affected part must be included between two curved incisions, meeting above and below at the points already indicated. By a few touches with a broad-bladed scalpel, whilst the skin is kept upon the stretch, the tumour is separated from its scrotal attachments, and left connected merely by the cord, which must then be divided. In some cases it will be found advantageous to expose and divide the cord in the first instance before dissecting out the tumour from the scrotum, as in this way a better command over it is obtained. The *division of the cord* constitutes the most important part of the operation, for, unless care be taken, it may retract into the inguinal canal and bleed freely. This accident is best prevented by separating the cord cleanly from the sheath—more especially the cremasteric fascia—and seizing it with clamp forceps above the point at which the ligature is to be applied. The simplest method of ligature consists in transfixing the cord with an aneurysm needle and tying the two halves separately with stout silk, the ends of which are for the present left long. The cord is next divided about half an inch below the ligatures, and it is then allowed to retract slightly, in order to make sure that the ligatures are efficiently applied and that bleeding is not being prevented merely by traction. If no oozing takes place from the stump it is drawn gently down into view and the ends of the ligatures cut off.

Another method consists in picking up the vessels separately in forcipressure forceps, and applying a fine ligature to each. The veins must be tied as well as the arteries. The arteries requiring ligature are usually the spermatic, the cremasteric, and the artery of the vas. The spermatic artery will be found in front, and the artery of the vas deferens behind. This method, which is far more tedious than simple transfixion, has been supposed to be followed by less pain than when the nerves of the cord are included in the ligature. I have not, however, found that much pain is complained of after the ligature *en masse*, and in castration for malignant disease this method certainly has the advantage that it allows the Surgeon to divide the cord at a higher level than he would otherwise do, especially if the incision be prolonged upwards and outwards, and the inguinal canal opened.

In castration for tuberculous disease it is better to separate the vas deferens

from the other constituents of the cord and to divide it separately. If it be found diseased it may be drawn down and a further piece removed in the hope of getting above the disease.

A large number of vessels usually require ligature in the scrotum. All bleeding from this source must be very thoroughly arrested, otherwise the loose tissues of the scrotum may become distended with extravasated blood and very troublesome suppuration may result. After the operation the wound must be accurately closed with sutures and a drainage-tube inserted at its lower end.

There is one danger that may occur in castration in children. It is that in young subjects the processus vaginalis testis may not be obliterated, and that thus the peritoneum may be opened up into the wound on dividing the cord. In one case I have known this condition lead to fatal peritonitis.

In some cases considerable induration and tenderness persist in the position of the stump of the divided cord, and occasionally the ligatures set up irritation, and may lead to a small abscess, which refuses to heal until the ligatures have come away. After castration for tuberculous disease a chronic abscess may form around the cord, probably as the result of the vas deferens having been diseased above the point of division.

GENERAL DIAGNOSIS OF SCROTAL TUMOURS.

The diagnosis of scrotal tumours is not only of considerable importance, but is often attended with very great difficulty; the more so, as they are frequently associated with one another, so that much tact and care are required to discriminate their true nature. Thus, it is not uncommon to find a hydrocele and a hernia; a hydrocele and a varicocele; or these affections co-existing with a solid tumour of the testicle. In other cases, again, as in Fig. 957, a carcinomatous tumour may co-exist with a hydrocele of the tunica vaginalis, and with an encysted hydrocele of the cord; and the different forms of hydrocele may occur together.

Tumours of the scrotum may, from a diagnostic point of view, be divided into two distinct classes:—
1, the Reducible; and 2, the Irreducible.

1. **Reducible Tumours.**—These are Hernia, Congenital Hydrocele, Diffuse Hydrocele of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure and by the patient lying down; re-appearing on the removal of the pressure, or on his assuming the erect posture. The mode in which the tumour disappears tends greatly to establish its diagnosis; though the general character of the swelling, and the history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse on coughing, &c. On reducing the tumour, it will be found that its return into the abdomen is accompanied by a gurgling noise, and by the sudden slip upwards of an evidently solid body. In the other reducible tumours, the

Fig. 957.—Carcinoma of the Testicle with Hydroceles of the Tunica Vaginalis and of the Cord.

proliferation of the epithelium; both the intertubular growth and the proliferated epithelium afterwards undergoing fatty degeneration, and forming cheesy masses.

Prognosis.—The prognosis of tuberculous disease of the testis is extremely bad. Treatment is of little if any avail, and the patient in the great majority of cases dies sooner or later of disease of the lungs, from general acute tuberculosis or from extension of the disease to the bladder, prostate, and even to the kidneys. In some cases, however, after the abscesses have burst, the cavities may heal, and the testicle remain withered, but free from active disease.

Treatment.—The more I see of this disease the more convinced I am that the sooner the diseased organ is removed the better will be the patient's chance of prolongation of life. The danger of infection of the system by acute tuberculosis from a tuberculous testis is so great, that when once the diagnosis has been made castration should not be delayed. In most cases however the operation is at best calculated to give the patient only temporary relief, as the disease usually extends along the vas deferens beyond the reach of the knife, and will continue to progress in the vesiculæ seminales and prostate, unless the patient succumb early to tuberculous disease of the lungs or brain. Before undertaking it, the urine must be examined for pus, and the state of the prostate and vesiculæ seminales ascertained from the rectum, as the operation would, of course, be useless if the affection of the testicle were merely a part of tuberculosis of the whole genito-urinary tract. Should the patient decline to submit to the operation, or his health be so bad that its performance is not advisable, the treatment must be conducted on general principles: alteratives, tonics, especially the iodide of iron, with cod-liver oil, and general hygienic means calculated to improve the health, must be steadily persevered with. Local applications are of little avail. The abscesses must be opened when they form. The cavity should be thoroughly scraped out with a sharp spoon and dressed with iodoform. Under this treatment it sometimes heals rapidly, but the cure is rarely permanent. If fungus form, it is of little use to try to treat it by the methods before described; if the body of the testis be deeply infiltrated with tubercle, no good could result.

Syphilitic Disease of the Testicle.—The testicle may be affected in the secondary and tertiary stages of the acquired disease, and also as the result of inherited syphilis in infants. In the secondary stage of acquired syphilis one or both epididymises are occasionally affected. In the later stages of the acquired disease, and also in the inherited form, the body of the testicle is primarily affected, and, as in other viscera, the simple inflammatory and the gummatous varieties are met with.

The **Simple Inflammatory Form**, which has been accurately described by Virchow, consists essentially of a chronic inflammatory overgrowth of the connective tissue between the tubuli seminiferi. The disease may uniformly affect the whole gland or be limited to localized patches. If the whole gland be affected, the organ slowly enlarges to perhaps more than double its natural size. The enlargement will be found to affect the body of the gland, the epididymis undergoing but little if any change; in fact, it may be so far concealed by the thickening round it as to be scarcely recognizable. The cord and vas deferens are unaffected. The body of the gland feels hard, almost cartilaginous, and the surface is smooth or perhaps slightly irregular. There is no pain, except a dragging sensation in the groin due to the increased

weight of the testicle. There is little or no tenderness, and in the more advanced stages testicular sensation is absent. There is no tendency to softening or to the formation of abscess. The disease is almost always accompanied by hydrocele, but at the same time adhesions may exist at various parts between the parietal and visceral layers of the tunica vaginalis, dividing the fluid into two or more portions, or limiting it to a small part of the surface of the testicle. Most commonly only one testicle is affected, but both may be attacked. In the localized form the induration is limited to one or more portions of the gland, the remainder being soft and healthy.

Structure.—On making a section from before backwards, the following appearances are found : If hydrocele exist, the tunica vaginalis will be opaque and thickened, and probably adherent at various points to the surface of the testicle. If no hydrocele be present, the tunica vaginalis may be uniformly adherent. The tunica albuginea will always be found greatly and irregularly thickened, and from it proceed opaque white dense fibroid processes into the substance of the gland. These may in extreme cases be so abundant that no healthy gland substance can be seen between them ; in less severe cases,

2

Fig. 962.—Syphilitic Gummata of the Testis. a, b, Gummata cut across : c, Section of Globus minor : and d, Cord.

patches of healthy tubular substance are found at various parts of the organ. A process of cicatricial contraction taking place in these fibroid processes may lead to a dimpling of the surface of the organ. The microscope shows that the change is due to an inflammatory small round-celled growth, which afterwards undergoes a development into a dense fibroid tissue, situated in the connective tissue between the tubuli seminiferi (Fig. 952). The new growth separates and presses on the tubules, and may cause their destruction in large areas.

The **Gummatous Form** is an aggravation of that just described, and presents the same symptoms, with the addition of those caused by the presence of the gummata. These form hard craggy nodules on the surface of the gland, the irregularities so produced being much greater than those arising from simple fibroid induration. The gummata have little tendency to soften, and discharge externally ; yet in rare cases they may do so.

Structure.—On making a section of a gland in this condition, more or less of the fibroid induration, above described, will always be found combined with thickening of the tunics of the testicle. The gummata vary in size, from a pea to a hazel-nut. They are of an opaque yellow colour, irregular

shape, and dense leathery hardness. They may be tolerably sharply circumscribed to the naked eye, but are usually surrounded by a zone of fibrous induration of an opaque white colour. The microscope shows around them the same small-celled growth above described, situated between the tubules. The new growth is vascular in the most recent parts. In the older parts the changes described in the chapter on Syphilis (Vol. I., p. 1133) may be seen in their walls, causing their gradual obliteration. Nearer the centre the tubules are found to be pressed upon and destroyed, and the cells of the new growth commence to undergo degeneration; until, in the yellow part of the gumma, nothing but granular *débris* is to be recognized. The gummata may be distinguished from tubercle by their greater toughness and more opaque yellow colour. Tubercle is rarely limited to the body of the testis; gummata, on the other hand, are rarely limited to the epididymis.

Prognosis.—If the disease be recognized and treated early, complete recovery

Fig. 958.—Syphilitic Testis. a. Tubuli Seminiferi; b. A part of the round-celled growth beginning to undergo fatty degeneration (180 diam.).

may confidently be hoped for; although relapses are of frequent occurrence. In the more advanced stages, the prognosis is not so hopeful, for, although under proper treatment the new growth may be absorbed, the gland will remain shrunken, puckered, and indurated. This is only what would be expected; for the tubuli seminiferi, as above stated, become more or less extensively destroyed by the pressure of the new growth in the later stages of the disease.

The **Treatment** is that recommended in Chapter XXXVI. for constitutional syphilis. Locally, the hydrocele may be tapped (but on no account injected), and pressure may be applied, by strapping over some mercurial ointment.

Diagnosis of the Simple, Tuberculous, and Syphilitic Enlargements.—The diagnosis of these affections is in some cases easy, in others very difficult. Whatever the form of disease may be, if it be complicated by hydrocele, this may first be tapped in order that the gland may be accurately examined. The hydrocele in these cases may not be translucent, as the tunica vaginalis is often thickened. It must be remembered that hydrocele is a very rare complication of carcinoma, or of adenoma; it is rare with tuberculous disease; less rare with simple chronic orchitis, and very common with syphilitic disease.

From hæmatocele and tumours, the diagnosis may be made by attention to the rules laid down on p. 1266. It having been determined that the swelling is due to one of the three above-mentioned causes, it remains to ascertain which it is. This may be done by attention to the following points: The cord is often thickened and tender in simple chronic orchitis; in tuberculous disease, the vas deferens alone is affected, being frequently considerably enlarged; in syphilis the cord is perfectly healthy. In simple chronic orchitis, the epididymis may be swollen, but the chief enlargement is in the body; in tuberculous disease, the epididymis is almost always the starting-point of the disease, and is enlarged more than the body; in syphilis, the body is first and almost exclusively affected. In chronic orchitis, the enlargement is usually uniform and smooth, and fluctuation is rarely present; in tubercle, the enlarged epididymis is craggy and nodular, and spots of softening may be felt; in syphilis, the body of the gland is greatly indurated, often nodulated, and softening is very rare. The testicle is usually painful and tender in chronic orchitis; in tubercle it is sometimes tender, seldom painful; in syphilis, it is almost invariably perfectly painless, and free from tenderness. The constitutional condition of the patient should also be carefully inquired into. Chronic orchitis usually arises as a sequence of injury, or perhaps gonorrhœa, in patients possibly strumous, gouty, or rheumatic; tuberculous disease occurs almost always in cachectic subjects, with a tuberculous history and a tendency to phthisis. The lungs should therefore be carefully examined. In syphilis, the ordinary symptoms of constitutional syphilis may be present, or a syphilitic history may be obtained. In tuberculous disease, the vesiculæ seminales may often be felt through the rectum to be enlarged, and nodules of tubercle may be felt in the prostate.

TUMOURS OF THE TESTIS.

SIMPLE TUMOURS.—**Adenoma**, or, as it has been called, *Cystic Sarcoma*, is the most common non-malignant tumour of the testicle.

Structure.—The essential feature of this tumour is the presence of cysts, varying in size from a cavity just visible to one as large as a walnut. Between these cysts is a varying amount of solid tissue. The whole tumour lies within the distended tunica albuginea, but will be found to possess a delicate capsule of its own, between which and the tunica albuginea is a delicate layer of a pale yellowish-brown colour, composed of the tubular substance of the testicle spread out over the mass of the growth. The attachment of the tumour is towards the mediastinum testis, and this suggests that the growth springs from the region of the rete testis, the cysts being believed to be derived from the obstructed and dilated tubes of that part of the gland.

Microscopic examination shows that the cysts are lined with an epithelium, sometimes small and cubical, sometimes flattened. The interstitial tissue is composed of young connective tissue in various degrees of development.

This is the typical structure of adenoma testis, but various modifications are met with. In the first place, the proportion of cysts to stroma varies greatly. The contents of the cysts may be clear and thin, or mucous and tinted, or stained with blood. More rarely they are filled with an atheromatous pulp. Occasionally some of the smaller cysts are filled with laminated epithelium, forming pearl-like bodies.

The stroma may be purely composed of spindle cells, or spindle and round cells mixed, or spindle cells with a good deal of fibrous tissue between them. Almost invariably cartilage is present. It is usually in tortuous columns,

which are clearly visible to the naked eye, and can be picked out of a thick section with a needle. It has been suggested that these columns of cartilage are lying in dilated lymphatics, but careful microscopic examination suggests rather that they are formed by chondrification of the embryonic matrix. The matrix in other cases may assume a myxomatous form, the intercellular substance being mucous in appearance and the cells stellate in form. In many cases the intercellular substance sprouts up into the cysts, forming intra-cystic growths still covered with epithelium. These tumours are usually simple and distinctly encapsuled, but in some cases they become malignant. This may occur from an exuberant growth of the embryonic tissue of the stroma, or, according to Rindfleisch, actual cancerous transformation may take place, the stroma assuming the form of a cancer stroma and the epithelium of the spaces taking on the active growth

Fig. 954.—Adenoma of the Testicle. The external covering is the tunica vaginalis; the next layer is the tunica albuginea; the thin imperfect layer under this is the tubular substance of the testicle spread out over the true capsule of the tumour.

of a true carcinoma. Many of these variations may occur in different parts of the same growth.

Symptoms.—These tumours are most common in young adults or middle-

Fig. 955.—Section of an Adenoma of the Testicle showing the cysts, the embryonic interstitial tissue and the columns of cartilage.

aged men, and are often attributed to a blow. They cause a steady increase in the size of the testicle, unaccompanied by pain or tenderness. Their growth is of varying rapidity, but they often take a year or more to attain

any considerable size. They are firm and elastic, and fluctuating points can not uncommonly be detected in them. The cord is unaffected till a late period unless they become malignant. The epididymis is early flattened out by the growth and cannot be recognized. If not removed they may attain a very great size, and at last the skin covering them may give way and the growth may fungate and bleed.

Diagnosis.—The tumour is distinguished from hydrocele by its want of

Fig. 966.—Adenoma of the Testicle more highly magnified, showing the stroma composed of spindle cells and fibres, and the cyst lined with cubical epithelium and part of a column of cartilage.

translucency, its more globular form and its weight. All doubt may be cleared up by an exploratory puncture.

Treatment.—The only treatment is early removal, always preceded by an incision into the mass to make sure that it is not a hæmatocele or a hydrocele.

Enchondroma of the Testicle.—Cartilage, as before stated, is almost always present in the adenoma of the testis. It may, however, appear alone, in larger or smaller nodules, or infiltrating the gland. It usually commences in the body, and may invade the epididymis. According to Cornil and Ranvier, whenever it reaches any considerable size it is no longer purely cartilaginous, but is mixed with sarcoma tissue and complicated with cysts, so that both clinically and pathologically it merges into the disease just described as cystic sarcoma.

Fibroma has been recorded, but is of extremely rare occurrence.

Dermoid Cysts are occasionally met with in the testicle, usually in the body of the gland, causing atrophy of the tubular substance by their pressure. They are of course congenital, but are of very slow growth, and may not be noticed till adult life. They usually contain turbid fluid or an atheromatous pulp, often mixed with hairs. In other cases they may lie outside the gland in contact with the epididymis. A case of this kind occurred in University College Hospital lately in which the cyst, which was about the size of the normal gland, lay in contact with the globus minor. It was dissected away without injuring the gland, and was probably a scrotal dermoid which had become adherent to the epididymis.

In other cases foetal remains may be found in the cyst. One of the most remarkable of these tumours that I have seen was under the care of the late

John Marshall. The diseased organ, which was about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling. After removal Marshall found that the sac contained some foetal *débris*, and it was doubtless of an embryonic character. The patient, who was about thirty years of age, had been affected with the tumour from early infancy.

MALIGNANT TUMOURS.—**Sarcoma** of the testicle without the presence of the cysts just described is not very common. It is indistinguishable from cancer before removal, presenting the same rapid growth, and softness of structure, giving rise to a smooth elastic globular or oval enlargement of the testicle. It is usually met with in younger subjects than cancer, sometimes even in young children.

Its microscopic structure varies. Small round-celled sarcoma is by far the most common variety, and often runs a very malignant course. Myxo-sarcoma, with large spindle cells intermixed with it, has been described. In very rare cases tumours containing striated muscular fibres mixed with spindle cells have been found in the testicle. They exactly resemble the congenital tumours of the same structure met with in connexion with the kidney.

The *Treatment* consists in early removal of the gland by castration.

Carcinoma of the Testicle not unfrequently occurs, and is invariably of the soft glandular variety.

Characters.—Cancer of the testicle most commonly occurs in the first instance in the body of that organ, rarely, if ever, affecting the epididymis primarily. The ordinary characters of encephaloid are always well marked in this affection; and the tumour eventually fungates, becoming softened and pulpy. The mass on section is soft, pink in colour, with large yellow patches of fatty degeneration scattered through it. Its substance is often broken down in parts by hæmorrhage. It is impossible to distinguish it from a soft sarcoma without microscopic examination. The microscopic structure is that of a soft glandular carcinoma. The stroma is small in amount but extremely vascular, and encloses spaces of great size filled with large cells of irregular form.

A carcinoma of the testicle may rapidly attain a very considerable magnitude, becoming as large as a cocoa-nut in a few weeks or months. When of this size it is, of course, abundantly supplied with blood-vessels; consequently the spermatic artery and accompanying veins will be found a good deal dilated. The lymphatic glands in the neighbourhood speedily become enlarged, as may be ascertained by deep pressure in the flank. The inguinal glands do not in general become affected until the skin has become implicated by the process of the disease. It is then also that the cancerous cachexia rapidly develops itself.

The **Symptoms** of carcinoma of the testicle are usually somewhat obscure in the early stages, although they become clearly and distinctly developed as the disease progresses. It is most commonly met with after middle life. The patient first complains of some degree of dragging pain and weight in one of the testes, which on examination will be found to be indurated and enlarged, though preserving its normal shape. The enlargement continues until the testicle attains about the size and shape of a duck's egg, being somewhat tense and elastic, but smooth and heavy. As it increases in size, which it usually does with rapidity, it becomes rounded and somewhat doughy or pulpy

in parts, where, indeed, it may almost be semi-fluctuating, though in others it continues hard and knobbed. This alteration in feel is partly due to softening of the substance of the tumour, and partly to its making its way through the tunica albuginea. The scrotum is much distended, reddened, and purplish, and becomes covered by a network of tortuous veins; the cord may become somewhat enlarged, hard, and knotty. As the disease advances, the scrotum becomes adherent at some of the softened parts, ulceration takes place, and a fungus projects, which presents all the characteristic signs of fungus hæmatodes; it does not commonly happen, however, that the disease is allowed to go so far as this before removal. The pain is not very severe at first, but after a time assumes a lancinating character, extending up the cord and into the loins.

Treatment.—The only treatment of any avail in cancer of the testicle is the removal of the diseased organ. This operation is not performed so much with the view of curing the patient of his disease, which will probably return in the lymphatic glands or in some internal organ, as of affording temporary relief from the suffering and encumbrance of the enlarged testicle. It is therefore an operation of expediency, and should be done only in those cases in which the disease is limited to the testicle, the cord being free and the glands not evidently involved; so that, if recurrence take place, it may not be a very speedy one.

An **Undescended Testis** may become the seat of a tumour, just as it may be affected by inflammation. The combination of malposition of the organ and a tumour is necessarily rare. But its possible occurrence must be borne in mind by the Surgeon, as it may lead to the necessity of an operation for the removal of the diseased mass from the inguinal canal. Cases of this kind are recorded by Storks and J. M. Arnott. The tumour in the first case was as large as a cocoa-nut; in the second as a man's fist. Both were medullary. The operation consists in exposing the tumour by a free incision—if necessary, carried through the tendon of the external oblique—opening the tunica vaginalis, enucleating the mass, and tying with care the shortened spermatic cord, which would probably be the most difficult part of the operation. The possible co-existence of a congenital hernia must be remembered. But it is remarkable that peritonitis does not appear to be the chief danger of this operation. In neither of the cases above referred to did it occur, the patient dying of erysipelas in Arnott's case; of recurrent cancer, a year after the operation, in that of Storks.

SOLID TUMOURS OF THE SPERMATIC CORD.

Fatty Tumours are not very uncommon. They most commonly occur as small isolated masses near the inguinal ring. They grow slowly and are of no importance except from their resemblance to hernia. The tumour can be pushed through the external ring, but it has no impulse on coughing, nor is there the characteristic slip and gurgle of a hernia as it goes back. Large lipomata invading the scrotum as well as the cord have also been recorded.

Fibromata and Myxomata of the Cord have been recorded, but are merely pathological curiosities.

Sarcomata have also been met with in this region.

OPERATION OF CASTRATION.

This operation may be required for the various non-malignant affections of the testicle that have resisted ordinary constitutional and local treatment, and have become sources of great annoyance and discomfort to the patient ; in the early forms of malignant disease, also, it may advantageously be practised. Before the operation the parts should be thoroughly shaved, the skin cleansed, and a carbolized towel applied for two or three hours. The patient should be lying on his back on a suitable table, and the parts around the seat of the incision should be covered with towels wrung out in 1 in 20 carbolic lotion. The Surgeon should stand on the same side as the testicle to be removed, and should grasp it at its posterior part with his left hand, in order to make the scrotum in front of it tense. The incision should extend from the external abdominal ring to the lower end of the scrotum. If the operation is being performed for malignant disease the incision will have to be extended upwards, in order that the inguinal canal may be opened and the cord reached at as high a level as possible. If the disease, as often occurs in tuberculous cases, has involved the skin, the affected part must be included between two curved incisions, meeting above and below at the points already indicated. By a few touches with a broad-bladed scalpel, whilst the skin is kept upon the stretch, the tumour is separated from its scrotal attachments, and left connected merely by the cord, which must then be divided. In some cases it will be found advantageous to expose and divide the cord in the first instance before dissecting out the tumour from the scrotum, as in this way a better command over it is obtained. The *division of the cord* constitutes the most important part of the operation, for, unless care be taken, it may retract into the inguinal canal and bleed freely. This accident is best prevented by separating the cord cleanly from the sheath—more especially the cremasteric fascia—and seizing it with clamp forceps above the point at which the ligature is to be applied. The simplest method of ligature consists in transfixing the cord with an aneurysm needle and tying the two halves separately with stout silk, the ends of which are for the present left long. The cord is next divided about half an inch below the ligatures, and it is then allowed to retract slightly, in order to make sure that the ligatures are efficiently applied and that bleeding is not being prevented merely by traction. If no oozing takes place from the stump it is drawn gently down into view and the ends of the ligatures cut off.

Another method consists in picking up the vessels separately in forcipressure forceps, and applying a fine ligature to each. The veins must be tied as well as the arteries. The arteries requiring ligature are usually the spermatic, the cremasteric, and the artery of the vas. The spermatic artery will be found in front, and the artery of the vas deferens behind. This method, which is far more tedious than simple transfixion, has been supposed to be followed by less pain than when the nerves of the cord are included in the ligature. I have not, however, found that much pain is complained of after the ligature *en masse*, and in castration for malignant disease this method certainly has the advantage that it allows the Surgeon to divide the cord at a higher level than he would otherwise do, especially if the incision be prolonged upwards and outwards, and the inguinal canal opened.

In castration for tuberculous disease it is better to separate the vas deferens

from the other constituents of the cord and to divide it separately. If it be found diseased it may be drawn down and a further piece removed in the hope of getting above the disease.

A large number of vessels usually require ligature in the scrotum. All bleeding from this source must be very thoroughly arrested, otherwise the loose tissues of the scrotum may become distended with extravasated blood and very troublesome suppuration may result. After the operation the wound must be accurately closed with sutures and a drainage-tube inserted at its lower end.

There is one danger that may occur in castration in children. It is that in young subjects the processus vaginalis testis may not be obliterated, and that thus the peritoneum may be opened up into the wound on dividing the cord. In one case I have known this condition lead to fatal peritonitis.

In some cases considerable induration and tenderness persist in the position of the stump of the divided cord, and occasionally the ligatures set up irritation, and may lead to a small abscess, which refuses to heal until the ligatures have come away. After castration for tuberculous disease a chronic abscess may form around the cord, probably as the result of the vas deferens having been diseased above the point of division.

GENERAL DIAGNOSIS OF SCROTAL TUMOURS.

The diagnosis of scrotal tumours is not only of considerable importance, but is often attended with very great difficulty; the more so, as they are frequently associated with one another, so that much tact and care are required to discriminate their true nature. Thus, it is not uncommon to find a hydrocele and a hernia; a hydrocele and a varicocele; or these affections co-existing with a solid tumour of the testicle. In other cases, again, as in Fig. 957, a carcinomatous tumour may co-exist with a hydrocele of the tunica vaginalis, and with an encysted hydrocele of the cord; and the different forms of hydrocele may occur together.

Tumours of the scrotum may, from a diagnostic point of view, be divided into two distinct classes:—1, the Reducible; and 2, the Irreducible.

1. **Reducible Tumours.**—These are Hernia, Congenital Hydrocele, Diffuse Hydrocele of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure and by the patient lying down; re-

appearing on the removal of the pressure, or on his assuming the erect posture. The mode in which the tumour disappears tends greatly to establish its diagnosis; though the general character of the swelling, and the history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse on coughing, &c. On reducing the tumour, it will be found that its return into the abdomen is accompanied by a gurgling noise, and by the sudden slip upwards of an evidently solid body. In the other reducible tumours, the

Fig. 957.—Carcinoma of the Testicle with Hydroceles of the Tunica Vaginalis and of the Cord.

diminution and eventual disappearance under pressure are more gradual, and there is no reduction of the mass as a whole.

b. The gradual squeezing out of the contents of a **Congenital Hydrocele**, together with its translucency, and the early age at which it occurs, will establish its true character. It must be remembered, however, that herniæ in very young infants may be translucent if the gut contains little or no fecal matter.

c. In the **Diffuse Hydrocele of the Cord** there is a uniform semi-fluctuating swelling in and near the ring; in which, however, there is no gurgling. &c., no complete reduction, nor sudden disappearance, as in hernia. It is also less defined, and has a less distinct impulse on coughing.

d. **Varicocèle** may always be distinguished by its pyramidal shape, and its knotted, soft, and irregular feel. After being reduced when the patient lies down, it will, when he stands up, fill again, even though the Surgeon compress the external ring with his fingers. This sign, which distinguishes it from a hernia, occurs also in congenital hydrocele; from which, however, the varicocèle may be distinguished by the absence of translucency, the want of fluctuation, and the general feel of the tumour.

2. **Irreducible Scrotal Tumours** are of various kinds: such as Omental Hernia, Hydrocele, Hæmatocele, the various forms of Solid Enlargement of the Testicle. These tumours, though presenting certain characters in common, yet differ somewhat in the predominance of particular signs. Thus, the shape of the tumour is usually pyriform in hydrocele, globular in hæmatocele, and oval in enlargement of the testicle; though this is subject to much variation. The weight is least in hydrocele and greatest in solid enlargement, proportionately to the size of the tumour. The characters of the surface present considerable differences, being smooth and tense in hydrocele and hæmatocele; often irregular, hard, or knotted in the other varieties. The rapidity of the formation of the tumour is greatest in hæmatocele.

a. **Irreducible Scrotal Hernia** may be recognised by its irregular feel, by its impulse on coughing, by its occupying the canal and concealing the cord, and by the testicle being distinctly perceptible below it.

b. **Hydrocele of the Tunica Vaginalis** is recognizable by its translucency; and the amount of opacity conjoined with this will enable the Surgeon to distinguish the degree of enlargement of the testis, which is conjoined with it.

c. In **Hæmatocele** the tumour is of sudden or rapid formation, somewhat globular, opaque, but not very heavy or hard, and smooth upon the surface.

d. In **Solid Enlargements of the Testicle** the tumour is heavy for its size, frequently globular or irregular in shape, sometimes knobbed, and usually attended with a good deal of dragging pain in the groin, and frequently with some enlargement of the cord.

In these three forms of scrotal tumour, viz., hydrocele, hæmatocele, and solid enlargement of the testicle, the diagnosis can always be made at once from hernia, by the Surgeon feeling the cord free above the tumour.

The point of most importance in the diagnosis of solid enlargements of the testicle is to distinguish the malignant tumours, sarcoma and cancer, from other forms of disease. In malignant tumours, the rapidity of growth, the softness and elasticity of the mass, the implication of one testis only, and the early enlargement of the cord, with its indurated and knobbed condition, are

important signs; especially if the disease occur in young men. In a more advanced condition, the softening of the swelling at parts with a tuberculous condition of the rest, and the occurrence of fungus with speedy constitutional cachexia, will point to the malignant nature of the tumour. In cases of great doubt and difficulty an exploratory puncture may be made, when the contents of the groove in the needle or of the fine cannula will probably determine the character of the growth. In more than one instance, in which there was much obscurity, I have seen the true nature of the disease cleared up in this way.

SPERMATORRHŒA AND IMPOTENCE.

Various forms of debility, of loss of power, or of irregularity of action in the generative organs of the male, are confounded together under the terms **Spermatorrhœa** and **Impotence**. These conditions require a more careful consideration on the part of the educated Surgeon than they have hitherto received, as their existence is a source of much distress to the sufferer. They are certainly one cause of conjugal unhappiness, leading perhaps to infidelity on the part of the wife, and occasionally even to suicide of the husband. These affections, which are of extreme frequency amongst all classes of the community, have scarcely received that attention on the part of the profession generally which their importance deserves; the unfortunate sufferers thus are too often driven into the hands of those pestilent quacks who flourish in the metropolis, and infest almost every town in the country, by whom they are not unfrequently ruined in health as well as in purse.

The **Sexual Melancholia** that accompanies these conditions is one of their more striking characteristics. The patient is languid in manner, depressed in spirits, his countenance is pale and haggard, eye dull, expression listless, and he is devoid of all energy. He takes no interest in the ordinary affairs of life, his whole thoughts are concentrated on his own condition, and he feels himself degraded as being unfit for that duty which is alike the first and the lowest of man. This state of mind is commonly the result of some local irritation or disease, re-acting on a morbidly sensitive nervous system; and on examination, the Surgeon will commonly find some local condition that has been the starting-point of the mental malady. Balanitis, phimosis, or varicocele in the male are common occasioning causes. But the most frequent direct exciting cause is undoubtedly masturbation.

We may recognize at least three distinct varieties of generative debility in the male, which may in some cases amount to actual impotence: 1, True Spermatorrhœa, or Seminal Flux; 2, Spasmodic Spermatorrhœa, or Spermatospasmos; and, 3, Aspermia, or Want of Seminal Secretion.

1. **True Spermatorrhœa, or Seminal Flux**, is rare, and is met with chiefly between the ages of eighteen and thirty. It is commonly the consequence of masturbation, or of debility of the generative organs induced by gonorrhœa, or of the continued struggle to repress the natural sexual desires by a life of enforced continence. In this condition there is a mixture of irritability and of debility. The generative organs are excited by slight emotional causes, or by trivial and ordinary physical stimuli—a thought, a look, a word, the movement of a carriage, the effort of straining at stool, will excite the secretion of the testes, which the debilitated state of the parts allows to escape with a feeble ejaculatory effort, or in a kind of leakage of a few

drops from the urethra. In the slighter cases, and in the earlier stages of the malady, these emissions take place but occasionally—three or four times a week, chiefly in the morning, in the mid-state between waking and sleeping, and are preceded by an erection. In the more advanced stages, the emissions occur once or oftener in the twenty-four hours without an erection; the semen at last, when discharged, flowing back into the neck of the bladder, escaping with each discharge of the urine, or being squeezed out after defecation. The patient's physical and mental state becomes seriously implicated in these more advanced cases of true spermatorrhœa. His countenance is pallid, anæmic, and sallow; his features are drawn, their expression is listless; his eyes lifeless; his spirits depressed, often to the lowest depths of despondency and despair. Connexion is impracticable, as the discharge of semen takes place either before erection occurs, or without its occurrence.

Diagnosis.—The first point in making a diagnosis is to ascertain that there is some real disease, and that the patient is not merely the subject of hypochondriasis or sexual melancholia. Various conditions are mistaken for spermatorrhœa by a nervous patient. The white discharge of phosphates occurring at the end of micturition (p. 1029), when the urine is alkaline in some forms of dyspepsia, is often believed by the patient to be seminal fluid; and as this condition is frequently accompanied by the languor of dyspepsia, and is common in those who sit up too late at night and overwork themselves, this harmless condition may give rise to the deepest mental depression.

Prostatorrhœa (p. 1140) is very apt to be confounded with spermatorrhœa; but the diagnosis may always be effected by a microscopical examination of the discharge.

An occasional involuntary emission is not spermatorrhœa. It is common to young men of excitable temperament, and is often the occasion of much groundless alarm. It occurs at that period of life when the generative power is at its highest development. It is simply the result of a hypersecretion of the testes and overflow of the semen. For it, early and congenial marriage is the only remedy. Unless this be adopted, Nature will assert herself. "*Naturam expellas furcâ, tamen usque recurret.*"

The escape of a small quantity of seminal fluid from the vesiculæ seminales while straining at stool is of common occurrence in young men leading a continent life; it need cause no anxiety, and requires no treatment beyond a purge and a cold hip-bath.

Frequent nocturnal emissions in many cases are merely a symptom of dyspepsia, the languid feelings of which the patient complains being very often due to this much more than to the loss of semen. The loss of semen by an involuntary emission causes no more depression than a corresponding loss during coition, and if occurring not more than twice a week has no evil effect. It is the constipation and dyspepsia accompanying it that are the real source of the symptoms.

Treatment.—The curative treatment of true spermatorrhœa should consist in giving tone to, and in lessening the irritability of, the genito-urinary organs. With this view, the preparations of iron, phosphorus, nux vomica, and cantharides will be found the most effective. The syrup of the phosphate of iron and strychnine, or the tincture of the perchloride of iron, in combination with those of nux vomica and cantharides, will be found of the greatest service. But under any form of treatment the cure will be slow, and long-

continued perseverance in the use of remedies is imperatively necessary. In addition to these means the cold hip-bath should be assiduously employed. This the patient should use every night and morning; remaining in it, at first, for about three minutes, but gradually increasing the time of immersion to ten or fifteen. In some cases the cold shower-bath appears to give more tone, and then should be preferred. The patient must sleep on a hard mattress, be lightly covered, and eat no supper. Some satisfactory mental occupation should also be provided, or travelling if possible. These means, useful as adjuncts, will not, however, cure the patient. For this purpose, the local irritability must be removed by the application of nitrate of silver to the prostatic and bulbous portions of the urethra. It will usually be found that there is a good deal of tenderness in these situations, felt on pressing upon the perinæum, or on passing an instrument into the urethra, when, as the point enters the bulb, the patient will suffer much pain. The continuance of this irritation certainly keeps up the seminal emissions, and thus maintains the debility of the genital organs, and the nervous irritability, that are so characteristic of these cases. It may most effectually be remedied by the application of nitrate of silver, as originally recommended by Lallemand. I have employed,

Fig. 958.—Syringe-catheter for applying Caustic to the Urethra.

with much advantage in such cases, the instrument here figured (Fig. 958). It consists of a silver catheter, having about a dozen minute apertures near the end. In the interior is contained a slender piece of sponge, about two inches long, fixed to the expanded end of a firm stylet that moves with the catheter. The instrument is charged by filling the sponge with some solution of nitrate of silver by withdrawing the stylet. It may then be well oiled; and, being passed down to the spot to be cauterized, the solution is forced out of the aperture by pushing down the rod, which compresses the sponge. I have found this syringe-catheter far safer and more manageable than Lallemand's or any other *porte-caustiques* that act by protruding a spoon or sponge, which is apt to be grasped by the spasmodic action of the muscles of the part, often being returned with difficulty into the shaft, and not without risk of lacerating the mucous membrane. I generally use a solution of the strength of 3j of the nitrate to an ounce of water; though sometimes only a half or a third of this strength can be borne. The application usually occasions a good deal of irritation for a time, sometimes even a muco-purulent discharge, and can be repeated only at intervals of from ten days to a fortnight. Any undue amount of irritation, particularly after the application, must be subdued by ordinary treatment. After the nitrate of silver has been used two or

three times, the treatment may be advantageously continued by passing twice a week a similar instrument charged with glycerine of tannin. This acts as an admirable astringent, and often acts better than the nitrate.

2. **Spasmodic Spermatorrhoea**, or **Spermatorrhea**, more frequently occurs between the ages of twenty-five and forty. It is frequently predisposed to by residence in a warm climate, or by the existence of some disease about the generative organs, such as stricture, varicocele, neuralgia testis, &c. In these cases there is not, properly speaking, a seminal flux; but complete connexion cannot be effected, as erection and ejaculation are either simultaneous acts or the erection partially subsides before the emission takes place. This form of generative debility is often as much dependent on mental as on purely physical causes.

Treatment.—This is a condition of irritability rather than of debility. It often occurs in strong and otherwise healthy men, accustomed to field-sports and out-of-door exercises. There is no evidence of anæmia or of debility of any kind. Hence tonics are not necessary. The remedy most to be relied upon is bromide of potassium in doses of 20 to 30 grains, with cold bathing. and, perhaps, when there is urethral irritation, blisters to the perinæum and along the penis, and belladonna to the interior of the urethra. In addition to these means, it is of the first importance to enjoin moderation in food and drink, and above all, avoidance of alcoholic stimulants.

3. **Impotence** arising from absence of all sexual desire or power, or from premature decay of that power, is not unfrequently met with, and often in individuals who are otherwise strong and healthy; sometimes, indeed, in those endowed with great muscular power, and much given to athletic exercises. This want of sexual desire may be looked upon in many instances as a natural deficiency in the organization of the individual, for which treatment can do little. In other cases it arises from exhaustion of the nervous system by habitual physical or mental over-exertion, by excessive sexual indulgence, over-training, or study carried to an injurious degree. Complete absence of seminal secretion—*Aspermia*—except in cases of atrophy or absence of the testes, must be especially rare. In a patient of mine who died at 54 years of age, and who, according to his own and his wife's account, had been completely impotent for twenty-four years, spermatozoa in considerable quantities were after death found in the testes, which were carefully examined with the view of ascertaining whether they ever secreted semen. Retention of both testicles, or atrophy of both glands from mumps, may cause impotence. Temporary impotence from nervousness is not uncommonly met with in young men immediately after marriage. In these cases the treatment recommended by Astley Cooper, of ordering some harmless medicine, and forbidding the patient to attempt connexion, will usually be effectual.

Sterility in the male is a condition that has attracted some amount of attention of late years. It is, of course, not unfrequently connected with, and is probably dependent on, the same conditions that give rise to the various forms of sexual debility that have just been described. But it may occur independently of any of these states—in individuals, indeed, who are possessed of a very considerable amount of sexual desire and vigour. It would appear to be due to some morbid condition of the seminal fluid, in consequence of which the spermatozoa are either absent, or are possessed of insufficient vitality to effect impregnation. The causes of this condition are very obscure; but over-

indulgence in sexual intercourse appears to be amongst the most frequent. It would seem as if each individual were endowed with a certain amount of procreative power, which, if early exhausted, or habitually wasted in indiscriminate intercourse, cannot be restored. Hence, polygamists in the East, or their Western congeners, do not propagate, as a rule, more than the average number of children. Amongst organic causes of this state, chronic epididymitis appears to be the most frequent (p. 1235). The only *Treatment* that can be adopted with any prospect of success, is, in the one case, prolonged avoidance of sexual excitement, and in the other, the removal of local disease existing in the urethra or testis, such as stricture, or thickening or condensation of structure, by the long-continued use of absorbent remedies on general principles. Tonics are valueless in such cases.

Sterility arises also from malformation of the penis, such as complete hypospadias, and more rarely from the size of the male organ rendering complete coition impossible.

In conclusion, I need scarcely say that, in the treatment of that general melancholia or hypochondriasis which accompanies these various affections, much good may be effected by means that directly influence the spirits and the mental condition of the patient. He should be encouraged to travel, to occupy himself with healthy out-door pursuits and amusements, to take regular exercise, to avoid all enervating habits; and, above all, his mind should be cheered by the hope of eventual cure. Should there be any local disease, such as balanitis, phimosis, or varicocele, that should be subjected to treatment or operation.

CHAPTER LXXIV.

DISEASES OF THE FEMALE GENERATIVE ORGANS.

By W. A. MEBEDITH, C.M., M.B.

SOME important surgical affections of these organs, such as vesico-vaginal and recto-vaginal fistulæ, lacerated perinæum, &c., have already been discussed. The remaining affections, implicating the Vulva, the Vagina, the Uterus, and the Ovaries, are of the greatest practical interest; but, as their full consideration would lead me far beyond the limits that can be assigned to them in this work, and indeed, belongs to another department of Medicine, I must content myself with a brief indication of the principal surgical points deserving attention.

INTRODUCTION OF INSTRUMENTS.

Speculum Vagins.—Vaginal specula of various shapes and materials are commonly used by Surgeons. For examination of the os and cervix uteri, the most convenient and generally adaptable instrument is the ordinary cylindrical glass speculum (Fig. 959), of which the inner mirror-like surface reflects a strong body of light into the bottom of the tube. It has the additional advantage of being readily cleansed, and is not stained by iodine solutions. A similarly shaped instrument—made of box-wood—is useful for the protection of the vaginal wall during application of the actual cautery to the cervix. For exploring the vaginal canal in cases of fistula, &c., recourse should be had to the metal duck-billed speculum, or to one or other of the bivalve varieties of this instrument.

Fig. 959. — Cylindrical Speculum.

Introduction of the Speculum can readily be effected without unnecessary exposure. There are two positions in which the patient may conveniently be placed for this purpose. In the first, she lies upon her back with the nates well raised and brought to the edge of the bed or couch, her knees apart, and her feet resting on two chairs; the Surgeon, standing or sitting in front of her, separates the labia with the thumb and forefinger of his left hand, and then passes the speculum gently and steadily between and under them, exerting any pressure that may be required *backward* on the perineum. This position is in some ways the most convenient for inspection, and for the local application of remedies; but it is often objectionable to the patient, as it appears to entail much exposure, although in reality it need not do so. The other mode of introducing the speculum, which should always be adopted when practicable, consists in placing the patient on her left side in the semi-prone position, with her left arm drawn backwards beneath her and

the knees well flexed, so as to bring the nates close to the edge of the couch; the instrument is then introduced in the same manner as before, the Surgeon sitting *behind* the patient. In whichever way the speculum be used, no force should be employed; the patient should be placed opposite a good light, and care should be taken that the instrument be introduced fairly to the cervix, the position of which may previously have been ascertained by tactile examination.

Female Catheter.—The use of the catheter is often required in various diseases, and after operative procedures involving the genito-urinary organs of women. It should be introduced without exposure, by the aid of touch alone—the patient lying on her back with the knees well flexed and somewhat separated. The Surgeon, standing at the right side of the bed, passes his right index finger within the orifice of the vagina and feels the urethra like a cord beneath the arch of the pubes; on tracing this forward, the meatus urinarius, situated immediately above the vaginal outlet, may readily be detected, and the catheter, held in his left hand, is then slipped into the urethral canal along the palmar surface of his right forefinger. The female silver catheter, as generally supplied, has the disadvantage of not readily admitting of

Fig. 960.—Self-retaining Female Catheter (Vulcanite).

thorough cleansing; and, for all practical purposes, the ordinary male gum-elastic catheter—No. 8 or 9—answers equally well. Whichever form of instrument be employed, it should be thoroughly flushed through with plain water immediately after use in order to ensure the removal of any vaginal mucus which may have lodged in it, and be subsequently washed in some antiseptic before being put away. When in constant use, as after certain operations, the catheter, after being washed, should always be kept immersed in an antiseptic solution—of 1 in 20 carbolic acid in the case of a metal instrument, or of 1 in 1000 corrosive sublimate lotion for a gum elastic one. For cases requiring retention of a catheter within the bladder, recourse may be had to the instrument here depicted (Fig. 960), which is fitted, when in use, with a length of rubber tubing through which the urine flows into a vessel beneath the bed containing some antiseptic fluid.

DISEASES OF THE EXTERNAL ORGANS AND VAGINA.

The **Vulva** is liable to numerous morbid affections, most commonly of inflammatory origin.

The **Labia Majora**, when involved in the *acute inflammation* accompanying an attack of gonorrhœa, especially in young, full-blooded women, may

occasionally become the seat of an abscess originating in the vulvo-vaginal gland, and requiring evacuation by a free incision on the inner aspect of the affected labium. *Chronic inflammation* of specific origin, or resulting from prolonged irritation caused by the presence of a concealed fissure or ulcer, may induce a kind of solid œdema, sometimes leading to considerable hypertrophy of one or both labia. This condition is usually curable in its early stage by removal of the source of irritation which has led to it; but when of long standing, it may occasionally necessitate surgical interference. The disease known as **Noma** or **Gangrenous Vulvitis**, occurring in young, badly-fed children, has been referred to elsewhere (Vol. I., p. 935).

Large Condylomata or **Verrucae** are often met with here as a result of syphilitic or gonorrhœal disease, and if neglected, may ultimately form irregular pendulous masses requiring extirpation by the knife or scissors, or preferably by means of the cautery.

Fibro-cellular Tumours, originating as outgrowths from the natural structure of the labia, are occasionally met with, and may require removal by excision with Paquelin's cautery knife.

Squamous Carcinoma may develop on the labia, although its more common seat of origin is in the neighbourhood of the clitoris. It usually appears as a nodular growth, which soon ulcerates, forming a sore with raised indurated and sharply defined margins, bleeding readily. While the disease is yet limited, and the neighbouring glands are but slightly, if at all, involved, excision of the affected tissues by the knife, followed by a free application of the cautery, is the proper treatment to adopt.

Cystic Tumours of the labia are not unfrequently met with, and may sometimes resemble rather closely the ordinary form of labial hernia, with which, however, their incompressibility and irreducibility, as well as the absence of any impulse on coughing, will prevent their being confounded. These cysts, which require removal by a little simple dissection, usually contain a clear glairy fluid, the retained secretion of the vulvo-vaginal gland; sometimes, however, the fluid is turbid and of a dark brownish hue from admixture of blood. Tolerably free hæmorrhage from the vascular tissues of the labium may follow their removal, requiring for its arrest the use of the cautery, or the firm pressure of a pad secured by a T-bandage. Occasionally these cysts project on the *inner* surface of the vaginal orifice, in which situation a simple incision, followed by removal of an elliptical portion of the cyst wall, is usually sufficient to effect a cure.

Varix and **Hæmatoma**.—A varicose condition of the veins of the labia and adjacent structures, apart from pregnancy, is occasionally, though rarely, met with, and may require surgical interference, not only on account of the discomfort arising from it, but also in order to avoid the risk of the formation of hæmatoma by subcutaneous rupture of the distended vessels. Destruction of varicose veins in the region of the meatus urinarius can be effected with Paquelin's cautery, care being taken to protect the healthy mucous membrane from injury by the employment of a bone speculum. In cases requiring operation for the removal of greatly enlarged *labial* veins, the safe plan to adopt is that of transfixing the affected labium with a stout pin, and then strangulating the entire mass of diseased vessels by means of an elastic ligature. A *suppurating* hæmatoma of the labium should be carefully opened and thoroughly evacuated, and treated antiseptically.

Occlusion of the Vaginal Outlet in young children, due to congenital adhesion between the nymphæ, is a condition which usually occasions a good deal of anxiety to the parents. It may, however, easily be remedied by tearing through the adhesion with a blunt probe while the opposed nymphæ are forcibly separated by the thumb and finger of the operator's left hand; a small strip of oiled lint should be placed in the vaginal orifice to prevent reunion of the torn surfaces.

Imperforate Hymen in young adults is a congenital malformation causing serious inconvenience and even possible risk to life owing to the resulting retention of the menstrual secretion, which may accumulate to an immense extent, becoming gradually converted into a thick chocolate-coloured fluid of the consistence of treacle. The condition may not attract attention until the age of seventeen or eighteen, when the non-appearance of the menstrual flux, in spite of periodical constitutional disturbances, usually leads to an examination which reveals the cause of the obstruction. The hymen, as a tense elastic membrane, projects downwards between the labia owing to the pressure of the fluid distending the vagina, which may be felt *per rectum* as an elastic swelling filling the pelvis and occasionally extending upwards into the abdomen as far as the umbilicus, bearing the uterus as a small firm tumour on its upper surface.

Treatment for the relief of this condition is best undertaken about midway between the menstrual periods, as indicated by recurrence of the molimina. The operation required, unless carefully performed, is by no means free from risk. The patient having been placed in the lithotomy position, the parts are first thoroughly cleansed with an antiseptic solution. A small vertical incision, one inch in length, is next made in the region of the hymen by cautiously dividing the obstructing tissues until the retained fluid is reached. The use of Paquelin's cautery knife for this purpose is preferable to that of an ordinary scalpel, as tending to obviate risk of septicæmia. In opening the membrane, care should be taken to avoid injury to the urethra, an accident to be guarded against by ordinary caution. Once the opening is made, the fluid should be allowed to escape slowly without the assistance of any pressure whatever from above, in order to avoid the risk of rupturing the Fallopian tubes or any vascular adhesions around them, by promoting too rapid collapse of the distended sac. When the fluid ceases to flow, the vertical opening is to be enlarged by two lateral incisions converting it into the form of a cross, and the cavity may then be very gently irrigated by a stream of warm carbolized lotion (1—40). Finally, a small plug of iodoform gauze is placed in the newly-made orifice, and covered over with a pad of antiseptic wool, which should be changed as often as may be rendered advisable by the amount of discharge. The use of the catheter is usually required for a day or two after the operation. The patient should remain in bed for a fortnight.

Partially Perforate Hymen in young newly-married women is a condition which may occasionally call for interference; incision of the rigid membrane with a probe-pointed bistoury, followed by forcible dilatation under an anæsthetic, is the proper treatment in such cases. When severe spasmodic pain of the character usually described as *Vaginismus* is habitually induced by attempted coition, its origin, failing other causes such as urethral caruncle, small fissures or ulcerations, etc., may occasionally be traced to a hyperæsthetic condition of the remains of the hymen. In these cases, excision with curved scissors of a complete ring of the sensitive tissue at the vaginal orifice

will usually cure the condition ; and this the more surely, if followed by forcible dilatation and the introduction of a firm plug of iodoform gauze, which may be left *in situ* for several days.

Hypertrophy of the Clitoris and its prepuce may be met with as a rare congenital condition ; the organ being found enlarged and elongated, and in some cases even constituting a tumour of considerable size. Under such circumstances, excision of the abnormal clitoris with the help of Paquelin's cautery may be necessary on account of the irritation caused by it. Removal of a *normal* clitoris as a means of cure in cases of epilepsy and of erotomania is a procedure as unscientific as would be that of removing the glans penis for the cure of similar affections in the male. The operation, at one time recommended and practised, has been proved by the experience of the profession to be as useless in its results as it is unscientific in its principle. *Carcinoma of the Clitoris* requires excision of the diseased organ, to be followed by a free application of the cautery.

The most common affection of the *meatus urinarius* is that known as urethral caruncle or vascular growth, the treatment for which has been described elsewhere (Vol. II., p. 1185).

Perineal Abscess, occurring as a result of chill or of local injury, requires early incision with a view to avoiding burrowing of pus and possible formation of fistula.

Rupture of the Perinæum, caused by the passage of the child's head during parturition, is an accident of not unfrequent occurrence in the case of primiparæ. The after-importance of the injury, from a surgical point of view, depends upon the extent and depth of the laceration. If merely the soft tissues between the posterior commissure of the vulva and the margin of the anus have been torn through, the rupture is styled *incomplete* ; and the necessity for subsequent surgical interference will depend somewhat upon the co-existence of any prolapse of the posterior vaginal wall. Should this complication be present, a plastic operation for the repair of the torn perinæum and the restoration of the parts to their normal condition is the proper treatment to adopt. In cases where the laceration has extended onwards through the anal sphincter muscle, the condition is described as one of *complete* rupture—a much more serious state of things than that above alluded to, and one which imperatively demands surgical interference in consequence of the loss of control over the lower bowel involved by the injury. For a detailed description of the operation for repair of ruptured perinæum, the reader is referred to Vol. I., p. 898.

Prolapse of the anterior or of the posterior wall of the vagina is not unfrequently met with in hospital practice. In either instance the condition usually originates in continued neglect on the part of the patient with regard to regularity in emptying the bladder or the lower bowel respectively. Unless proper means be adopted to rectify the tendency to prolapse by due regulation of the patient's habits, combined with the use of astringent injections or pessaries and the wearing of some suitable form of "support," the condition may become extremely troublesome owing to gradual implication of the floor of the bladder in the prolapse of the anterior vaginal wall (*cystocele*), or of the rectum in the case of a protrusion of the posterior wall of the passage (*rectocele*). The two conditions not uncommonly coexist in varying degree in cases of uterine prolapse.

Operative procedures undertaken with a view to remedy a prolapse of the *floor of the bladder* by excising a portion of the mucous membrane of the anterior vaginal wall are by no means very satisfactory ; and the condition in question may generally be best treated by the wearing of an artificial support. In cases of *rectocele*, on the other hand, much benefit may be derived from the usual operation for the repair of ruptured perinæum, combined with the removal of a wedge-shaped portion of the redundant mucous membrane covering the prolapsed bowel, by which means the original outlet is narrowed and the protrusion supported.

A somewhat rare condition, termed *sacculated dilatation of the urethra*, in which the lower wall of this passage projects into the vaginal canal in the form of a small oval protrusion, causes much discomfort owing to the escape of the small amount of urine contained in the pouch subsequently to the completion of micturition. The proper treatment consists in excising an elliptical portion of the vaginal mucous membrane underlying the urethra, and adapting the edges with silkworm-gut sutures.

Congenital Absence of the Vaginal Canal is a rare malformation, usually associated with imperfect development of the uterus and its appendages, but occasionally met with in women otherwise perfectly well formed as regards the external organs of generation and the mammary development. The actual condition may be detected by digital exploration of the rectum while a sound is in the bladder : the two cavities will be found in close apposition without any intervening organs, the point of the bladder sound being felt thinly covered through the gut. **Complete Absence of the Uterus and Ovaries** can be further confirmed, if desirable, by combined rectal and abdominal palpation while the patient is deeply anæsthetized. No surgical interference can be entertained in such cases ; and none is required, as the imperfect development of the uterus precludes the possibility of any menstrual accumulation. The condition known as **Atresia Vaginæ**, or **Imperforate Vagina**, is one of congenital partial occlusion of the canal. The symptoms arising from it are identical with those caused by retention of the menstrual secretion in cases of imperforate hymen ; the chief distinguishing feature from this latter condition being the absence in these cases of any notable bulging of the hymen at the vaginal outlet—a fact accounted for by the thickness of the obstructing tissues.

Before attempting to restore the patency of the original canal, it is important to form a tolerably accurate idea of the depth of the obstruction and of the position of the distended sac by means of combined rectal and vesical exploration with a bladder sound. This latter should be retained *in situ* by an assistant in such a manner that the urethra and bladder may be kept well drawn upwards out of harm's way during the operation, while the Surgeon's left index finger in the rectum protects the bowel from injury, and serves as a guide in tearing through the septum.

A transverse incision is now made over the seat of the hymen—about midway between the urethra and the anus, and the obstructing tissues are gradually torn through by the right forefinger of the operator, aided by occasional touches with the scalpel or scissors, until the distended sac is reached. This is punctured and evacuated with precautions similar to those already recommended in cases of imperforate hymen. The newly-restored canal is then carefully packed with strips of iodoform gauze, which should be replaced at the end of twenty-

— DILATORS OF THE FEMALE GENERATIVE ORGANS.

THIS IS A TIGHT-FITTING vulcanite plug. This may be allowed to remain in the vagina for three or four days, when it is to be replaced by a similarly-shaped one of some size having a central perforation to allow of the escape of the menses. By means of these dilators, which are maintained in position by means of the everted rim, and thence passing upwards in the vagina, and being secured to a waistband, the canal is kept patent until it is fully dilated. The inevitable tendency to contraction of the newly-dilated canal must subsequently be kept within limits by means of a suitable pessary or by the occasional use of dilators.

A form of stricture is sometimes met with in which partial obliteration of the lower part of the vagina with occlusion of the cervical canal has resulted from inflammation following injuries inflicted during parturition. The stricture in such cases may occasionally be overcome by the forcible passage of a bougie. Should this prove impossible, a long exploring needle may be introduced through the obstruction into the uterine cavity while the cervix is secured by the beak of a tenaculum; a fine-bladed tenotomy knife is then introduced upwards into the cervical canal along the needle track, and the contracting tissues are divided in a radiating manner sufficiently to allow the introduction of a glass cannula, through which the retained blood is removed.

Various discharges connected with the female organs of generation fall under the observation of the Surgeon; they may proceed from the mucous membrane covering the external parts, or from that lining the vagina; or, again, from the interior of the cervical canal or of the uterine cavity. When they proceed from the *external organs* or the *vaginal canal*, these discharges are frequently, although not necessarily, of gonorrhoeal origin, and then require to be treated in the way that has been mentioned at p. 1173, Vol. II. When of a mucous nature, proceeding from mere excessive secretion from the mucous membrane of these parts, the use of astringent injections, combined with attention to the general health, will usually succeed in effecting a cure.

Discharges of a *purulent* character may occur in *young children*, as a result of constitutional debility. Occasionally such discharges lead to a supposition that the child has been improperly tampered with; and, although they may of course be occasioned by some violence inflicted on the genitals, they may be actually due to gonorrhoeal infection, it must be borne in mind that in the great majority of instances such symptoms arise solely from constitutional conditions, and are in no way referable to external causes. The treatment consists in attention to strict cleanliness, the use of warm lead lotion, and improvement of the general health, with removal of any local irritation, such as thread worms from the lower bowel.

Discharges dependent upon unhealthy conditions of the *cervix* and lining of the *uterus* usually require special treatment, for the details of which the reader may best refer to works devoted to the Diseases of Women. The consideration of the nature and management of *uterine displacements* will be found in a subsequent chapter.

TUMOURS OF THE UTERUS.

Fibroid, or more correctly **Fibro-myomatous Growths**, are the most common form of uterine tumour. Structurally, they

Consist of fibrous and of unstriped muscular tissue combined in varying proportions, and hence constituting growths of varying density, according to the relative preponderance of one or the other of these component elements.

The *ordinary fibro-myoma (hard fibroid)*, occurring either singly or as multiple formations in the body of the uterus, is characterized by a marked excess of the fibrous elements, which are commonly arranged in concentric bundles around one or numerous centres. The growth, of a more or less distinctly circumscribed nature, is usually directly continuous at one point with the uterine tissues, but is elsewhere surrounded by a layer of areolar structure, constituting what is known as its *capsule*. This latter contains numerous ramifying vessels, often of considerable size; but the vascular supply to the substance of the tumour, derived from vessels entering it at its uterine base, is as a rule comparatively scanty—a fact which accounts for the slow rate at which these tumours generally grow.

The comparatively rare type of tumour known as a *soft fibroid*, or true uterine *myoma*, and characterized structurally by a very great preponderance of muscular tissue, partakes more of the nature of a hypertrophic growth, inasmuch as its substance merges gradually into that of the surrounding uterine wall. A condition of this sort generally gives rise to a symmetrical tumour, which grows very rapidly, in consequence of its great vascularity, and is accompanied by profuse uterine hæmorrhage.

In the great majority of cases, ordinary fibro-myomatous disease of the uterus gives rise to no symptoms warranting surgical interference of any kind. The normal tendency of these tumours is to grow slowly until the age of the menopause is reached, and then gradually to undergo a process of natural involution, consequent upon their diminished vascularity, until they finally disappear completely. In a comparatively small proportion of instances, however, active treatment may become necessary as the best means of saving life under one or more of the following conditions, viz., persistent and uncontrollable uterine hæmorrhage; severe pain or other serious pressure symptoms caused by pelvic outgrowths; rapid increase in the size of an abdominal tumour (sometimes due to cystic or other degenerative changes).

In considering the question of *surgical treatment*, the ordinary classification of intramural or interstitial, subperitoneal, and submucous growths may conveniently be followed, always with the understanding that the two last-named are secondary developments of the intramural variety, the terms “subperitoneal” and “submucous” indicating the direction followed by the original growth in the process of its gradual extrusion from the substance of the uterine wall. As a general rule, it may be stated that the amount of uterine hæmorrhage induced by fibro-myomata is proportionate to the degree of enlargement of the uterine cavity caused by their presence, and is further dependent upon the propinquity of any growth to the mucous membrane lining the cavity. Thus, a pedunculated subperitoneal tumour may exist without the occurrence of any unusual menstrual loss, while a comparatively insignificant submucous or polypoid growth often gives rise to most persistent and alarming hæmorrhage.

The **Diagnosis** of a uterine tumour, apart from the symptoms of pain and hæmorrhage already alluded to, is to be arrived at by physical examination—notably by combined abdominal and vaginal (or rectal) palpation—by which means the consistence and contour of the growth are to be made out, and its continuity with the uterus definitely ascertained.

The **Operative Treatment** of uterine tumours varies somewhat, according to the site and connexions of the growth or growths.

The **Subperitoneal** variety, when unaccompanied by much co-existent enlargement of the uterine body, may occasionally require operative interference on account of the size of the tumour and the consequent peritoneal irritation caused by its presence. The operation usually performed under such circumstances is known as *Myotomy*, or more correctly as *Myectomy*. In the case of a *pedunculated* tumour, the growth, having been extracted from the abdominal cavity through a median incision, is supported by an assistant while the Surgeon secures the pedicle by means of a tightly applied ligature of stout silk: the two ends of this, threaded together on a straight needle, are then passed through the substance of the pedicle immediately above the level of the constricting ligature; the needle is withdrawn, and the threads brought round again on either side are firmly tied together above the knot of the first loop. The pedicle is now divided, and the cut edges of its peritoneal investment are sutured together across the face of the uterine stump with a view to avoiding the subsequent formation of adhesions thereto. In dealing with a *sessile* outgrowth, the body of the uterus should first be encircled temporarily by an elastic ligature for the purpose of controlling hæmorrhage. The tumour is then cut away, and a wedge-shaped portion is excised from its uterine base so as to leave two flaps of tissue with an outer covering of peritoneum; after being suitably trimmed down, these are to be accurately united face to face by three or four successive rows of fine silk sutures, the first row of which must obliterate the angle at the base of the flaps, while the last one unites the edges of the divided peritoneum.

The surgical treatment of tumours involving the body of the uterus entails the performance of one or other of two operations, known as *Oöphorectomy* and abdominal *Hysterectomy*.

Oöphorectomy, or **Removal of the Uterine Appendages** (ovaries and tubes), is an operation aiming at the premature induction of an artificial menopause, with the view of thus promoting the decrease and final absorption of the uterine growths. The procedure in question, compared with the alternative operation of hysterectomy, has the advantage of entailing much less immediate risk to life—its average mortality in skilled hands amounting to only about 5 per cent.; but, on the other hand, it must be noted that its ultimate results as regards the immediate arrest of hæmorrhage and subsequent wasting of the growth are not always completely satisfactory; and further, that it is not applicable in all instances—notably in the case of uterine myoma (soft fibroid), and in cases of large multiple tumours when the size and position of the individual growths may render it impossible to effect with safety the complete removal of the appendages.

The **Operation** is performed as follows: The abdominal cavity having been opened by the usual median incision, the Surgeon, standing on the right side of the patient, introduces the fore and middle fingers of the left hand and explores the surface of the tumour until he detects the position of the left ovary and tube, which should be firmly grasped between his two fingers, and thus brought up into view—a manœuvre to be somewhat facilitated, if the ovary be deeply situated, by drawing the summit of the tumour over towards the right side. When fully raised, the ovary and tube are securely held in the Surgeon's left hand, while he clamps the broad ligament well beneath the

ovary with a pair of large pressure forceps. A single-thread ligature of No. 4 silk is now passed through the broad ligament immediately below the forceps by means of a handled needle, which is withdrawn leaving a loop of silk on one aspect of the pedicle, and the two free ends of the ligature on the other. One of these latter is now carried round the outer edge of the broad ligament and passed through the projecting loop; the forceps are removed while an assistant holds up the ovary and tube; and the free ends of the ligature which thus encircles the compressed tissues by a twisted or figure-of-8 loop, are drawn upon firmly before being tied together at the inner border of the pedicle, and thence brought round on either side to be again united at the outer border, where they are finally cut short. The ovary and tube are then cleanly removed, and the stump is dropped in, the same procedure being subsequently repeated on the opposite side.

The operation of **Abdominal (Supravaginal) Hysterectomy**, involving removal of the entire mass of a fibro-myomatous tumour, including the body of the uterus with its appendages, should never be undertaken without the most careful forethought as to the necessity for its adoption. The possibility of discovering in any given instance of uterine tumour, when interference is

Fig. 961.—Serre-nœud with wire.

undertaken with the object of dealing with the uterine appendages, that their removal cannot be effected, and that resort must consequently be had to the major operation, should always be kept in view when considering the advisability of operative treatment in these cases.

The performance of hysterectomy in the case of a more or less symmetrical tumour not involving the lower segment of the uterus, although necessarily entailing risk to life, offers no very serious difficulty to any one accustomed to deal with abdominal growths. On the other hand, the removal of a multiple tumour with a broad pelvic base opening up the layers of one or both broad ligaments, is an undertaking which may tax to the utmost the knowledge and skill of the most experienced Surgeon.

The following are the steps of the operation in a case presenting no special difficulties of any kind. The tumour, having been turned out of the abdominal cavity, is held up by an assistant while the operator encircles the uterus, usually at or about the level of the junction of the body and cervix, with a flexible wire connected with the instrument known as Kœberlé's *serre-nœud* (Fig. 961). Both uterine appendages should be included in the loop, while care is taken that no portion of intestine be nipped by it, and that the bladder be kept well out of harm's way in front. The wire, having been properly secured, is tightened by means of the spiral screw sufficiently to control

hæmorrhage, and a stout pin (Fig. 962) is then passed through each broad ligament and through the uterine tissues immediately *above* the constricting loop, before cutting away the mass of the tumour together with the appendages. After this has been done, the distal portion of the uterine stump is carefully trimmed down, and the edges of its peritoneal investment including those of the divided broad ligaments on either side, are laced together across its upper surface by means of a continuous silk suture in order to prevent subsequent retraction. While these steps are being taken, the constricting wire should be further tightened by an occasional turn of the screw. The abdominal parietes are now adjusted carefully around the uterine stump supported externally by the transfixing pin, and the divided edges of the peritoneum are then united immediately behind the pedicle by a silk suture which also includes a small fold of the serous membrane covering the posterior aspect of the cervix uteri *below* the level of the wire ; by thus ensuring early adhesion between the serous surfaces referred to, the general peritoneal cavity is in great measure protected from infection through the strangulated tissues. All sponges are now removed from the abdomen with the exception of a flat one which serves to protect the cavity during the insertion of the sutures ; after its removal, the incision is closed and the wire is finally tightened again.

Fig. 962.—Transfixing Pin for Uterine Stump.

The uterine stump, having been well dusted with iodoform powder, is then packed round with pledgets of dry absorbent gauze, and the abdomen is covered with a dry dressing of some antiseptic material, to be kept in place by strapping and a flannel binder. If all go well, this dressing need not be disturbed for a week, at the end of which time all dressings should be removed and the distal portion of the stump trimmed down to the level of the pin. One of two methods may now be adopted : the *serre-nœud* may be daily tightened up until the wire finally cuts its way through the constricted tissues ; or the wire may at once be clipped through at its point of attachment, so as to allow of the withdrawal of the *serre-nœud* ; the transfixing pin is cut out from the face of the stump, and the expanded wire loop is then readily removed, leaving a slough which gradually separates in the course of from three to four weeks, as the cavity heals by granulation.

In the class of cases above referred to, as characterized by the presence of multiple growths involving the lower segment of the uterus, and expanding one or both broad ligaments, the operative details are necessarily much more complicated :—The ovarian vessels (artery and venous plexus) in each broad ligament are first to be secured in their continuity by a ligature of which the ends are afterwards cut short. If the bladder be drawn up over the front of the tumour, its upper attachment should be freed by a horizontal incision through the serous coat of the uterus, in order that the viscus may be peeled upwards sufficiently to allow of the application of an elastic ligature around

the base of the tumour at as low a level as may be possible, for the purpose of controlling the uterine arteries. The ligature in question should twice encircle the uterus so as to ensure even and continuous compression, its free ends being secured by a pair of pressure forceps, which can readily be removed should the ligature require tightening. A circular incision through the outer layer of uterine tissue is now carried horizontally around the tumour dividing the ovarian vessels in either broad ligament above the level of their ligature. While this is being done, the mass of the tumour is held forcibly upwards by an assistant in order to facilitate the enucleation of its base, which process is rapidly carried out until the remaining portion of uterine tissue is sufficiently reduced in size to admit of the application of the serre-nœud wire immediately *above* the groove occupied by the elastic ligature. This latter is removed as soon as the wire has been properly secured and tightened. The transfixion pin is then passed, and the mass of the tumour is cut away, usually leaving a somewhat bulky stump which, together with the remains of the uterine capsule, will require to be freely trimmed down before it is reduced to a convenient size. The subsequent management of the case is identical with that already described.

The treatment of the uterine stump by means of the serre-nœud, known as the *extra-peritoneal* method, is on the whole the most generally applicable as well as the safest plan for adoption in dealing with fibro-myomatous tumours. It, however, involves a somewhat protracted stage of convalescence in bed, lasting usually five to six weeks; and further, the operation is liable occasionally to be followed by a ventral hernia at the lower end of the scar.

Another form of treatment, termed the *intra-peritoneal* method, although involving more immediate risk to life, avoids the disadvantages above alluded to, and may sometimes be adopted successfully in suitable cases. In this operation, the uterine appendages having first been tied off, the body of the uterus is constricted by an elastic ligature, and the tumour is cut away. An antero-posterior wedge-shaped piece is now excised from the uterine stump, and any portion of mucous membrane remaining on the inner surface of the two flaps of uterine tissue thus formed is carefully dissected off down to the level of the constricting ligature. The opening of the cervical canal, after being thoroughly cleansed by the use of a strong solution of carbolic acid (1 in 10), is then accurately closed by a few points of suture including mucous membrane alone; these are to be cut short. The trunk of each uterine artery is next secured by means of a ligature passed from behind forwards through the base of each uterine flap, and thence returned through the corresponding broad ligament to be tied at its original point of entry. The two flaps of uterine tissue, having been thoroughly cleansed, are then united face to face by successive rows of buried sutures until the stump is completely closed in, a final series of stitches being employed to accurately unite the divided edges of its peritoneal investment. The elastic ligature is now removed, and if no oozing be seen, the stump is dropped in, and the abdomen closed in the usual way.

The **submucous** variety of fibro-myoma, when occurring as a single growth of a more or less sessile character projecting into and dilating the uterine cavity, may occasionally necessitate surgical interference in consequence of alarming and persistent hæmorrhage which has proved totally unamenable to ordinary gynecological treatment. Unless the cervix be expanded over the

protruding mass, preliminary dilatation of the cervical canal may advantageously be effected by the insertion of a sponge tent 12 hours previous to operation. This should remain *in situ* until the patient is placed on the operation table in the lithotomy position after having been anæsthetized. A free incision through the capsule of the presenting portion of the growth will then enable the operator to shell it out by a gradual process of enucleation, while firm suprapubic pressure is maintained by the hand of an assistant, in order to facilitate the extraction. This operation, often an extremely difficult and tedious one to perform if the growth is of large size, necessitating extraction piecemeal, is to be undertaken only for the relief of the most urgent symptoms in exceptional cases, since all submucous growths have a natural tendency to become polypoid in character, and thereby more easily removable.

The ordinary **fibroid polypus** is met with usually as an oval or pear-shaped growth attached to the posterior aspect or fundus of the uterine cavity by a more or less distinct pedicle. Such growths not uncommonly give rise to repeated and dangerous hæmorrhage, often altogether disproportionate to their size. The most efficient mode of treatment consists in removal by means of a wire écraseur, of which the loop is slipped over the polyp and then gradually tightened until division of the pedicle is effected. Unless the growth be protruding through the cervix, preliminary dilatation of this canal will be required in order to permit of the necessary manipulations.

Two other varieties of uterine polypi are met with, viz., the **glandular** and the **cellular polypus**. These grow from the cervix or its immediate neighbourhood, and their removal by simple torsion commonly offers no difficulty. It is an important rule, after all operations involving the cervical canal or the uterine cavity, to apply a strong solution of iodine freely to the interior of the womb, as the surest means of avoiding the risk of the subsequent development of any septic mischief.

Malignant Disease of the Uterus may develop in any one of the three following forms, viz., as Columnar Carcinoma ; as Squamous Carcinoma ; and much more rarely as Sarcoma.

Columnar Carcinoma, the most common form of malignant growth in this situation, is occasionally met with as a primary affection of the *body* of the uterus in women over fifty years of age. The disease, originating in the epithelium of the uterine glands, begins either as localized nodules in the substance of the uterine wall, or as a diffused fungating growth of the mucous membrane lining the cavity. The usual *symptoms* are pain, watery discharge, and hæmorrhage, the latter sign being most marked in cases of fungating disease. The uterine cavity is somewhat enlarged, and the os appears patulous on inspection ; but the cervical tissues generally remain normal to sight and touch. The only radical *treatment* consists in vaginal extirpation of the entire uterus ; but, in cases of fungating cancer in feeble women, removal of the intra-uterine growths with a curette will tend to prolong life by checking the hæmorrhage.

The more usual seat of origin of columnar carcinoma is in the *cervical* tissues where it may develop at any age between twenty and fifty-five. The disease commonly commences as a nodular growth in the wall of the cervix, thence tending to spread upwards into the body of the uterus, as well as both outwards and downwards, thus speedily involving the tissue of the

Broad ligaments and the vesico-vaginal and recto-vaginal septa with consequent early impairment of the natural mobility of the uterus. In course of time the pelvic viscera become completely fixed and surrounded by the new growth, in which the occurrence of ulcerative changes gradually causes destruction of the cervix and other tissues implicated, occasionally leading to the formation of vesical or rectal fistulæ. Finally, general constitutional cachexia ensues, and the patient dies from exhaustion. The earliest *symptom* of cancer of the cervix, as in fact of any form of the disease in connexion with the uterus, is hæmorrhage, either exceeding the natural loss; or recurring irregularly. Pain is by no means a constant symptom, and is usually absent so long as the growth is limited to the cervix. In the advanced stages of the disease, pain may occasionally be very severe, necessitating the habitual use of anodynes. Profuse watery discharges accompanied by foetor indicate ulcerative changes in the affected parts.

Treatment in advanced cases must necessarily be of a purely palliative nature; the chief indications being to control hæmorrhage, relieve pain, and to sustain the patient's strength.

In the earlier stages of the affection, attempts were formerly made to arrest its progress by excision or amputation of the cervix, followed by application of the cautery. Such methods can be of but little use in retarding the progress of the disease, although they may prove beneficial as a means of checking hæmorrhage and discharges in cases too advanced for the adoption of more radical measures. In suitable instances, *i.e.*, when the mobility of the uterus is still unimpaired, and no trace of deposit is to be detected in the adjoining tissues, recourse should be had without delay to one or other of the following operations, *viz.*, *supra-vaginal excision* of the cervix, or *complete extirpation* of the uterus.

The former of these consists in the removal not only of the entire cervix, but also of such portion of the uterine tissues above the level of the internal os as may be found implicated by the upward extension of the cervical disease. In this manner almost the entire organ may be excised, leaving merely a shell of the uterine wall with its serous covering intact. The earlier steps of the procedure are the same as those required in the operation for complete extirpation of the uterus; which may, therefore, be at once resorted to should such a course appear desirable. For a full description of the details of both these operations, the reader should consult the works of special writers on this subject, where statistics may be found, showing the relative mortality of the two procedures, and also the degree of protection against recurrence afforded by each one of them.

Squamous Carcinoma of the cervix differs essentially from the far more common *glandular* form of cancer above described, inasmuch as it begins as a *surface* growth and usually remains for a long time superficial without involving the deeper tissues. The disease originates in the stratified epithelium investing the *vaginal portion* of the cervix, or in the transitional cells immediately within the external os uteri; and tends to spread outwards and downwards on to the vaginal wall. When typically developed, it constitutes an irregular papillomatous growth—known as a *Cauliflower excrescence*—which bleeds readily on being touched. While still limited to the vaginal portion of the cervix, the disease may be eradicated by the operation above referred to as *supra-vaginal excision* of the neck of the womb; but if once the broad ligaments have been

invaded through extension of the growth to the vaginal vault, no radical interference can be undertaken, and the affection proves rapidly fatal.

Sarcoma is a comparatively rare disease of the *body* of the uterus. It is met with in middle-aged women, either as a diffused affection of the mucous lining of the cavity, or as circumscribed growths in the substance of the uterine wall—in either case tending to form compound polypoidal masses of greyish-white colour and pulpy consistence. The prognosis is always unfavourable, although the course of the disease is less rapid than that of true cancer. The removal of the intra-uterine growths after dilatation of the cervix, whether undertaken for diagnostic purposes or as a palliative method of treatment, should be followed by the application of strong iodine solution to the interior of the cavity. The only radical measure to be adopted in these cases is that of total extirpation of the uterus.

TUMOURS OF THE OVARY.

For clinical purposes, ovarian tumours may be broadly classed in two main groups. The first of these—including those growths in which cyst-development predominates—can be subdivided as follows : 1. Ordinary multilocular ovarian cysts, containing glairy fluid of a highly albuminous nature ; 2. Multilocular cysts, with colloid (jelly-like) contents ; 3. Dermoid cysts, containing sebaceous and fatty material, with hair growing from patches of true skin, bony plates, teeth, &c. ; 4. Papillomatous cysts filled with thin, watery, non-albuminous fluid, and showing more or less extensive patches of warty growth (papilloma) on the inner surface of the cyst wall. The second group above referred to, consisting of the solid tumours, includes—1. Fibroma ; 2. Sarcoma ; 3. Carcinoma.

Of the growths here enumerated, those included in the first group constitute the large majority of ovarian tumours, the ordinary multilocular cyst being by far the most common form ; the three next-named varieties occur much less frequently. The solid growths, named in the second group, are comparatively rare.

Tumours of the ovary may develop at almost any age, being occasionally met with in quite young children, and not very uncommonly in women who have long passed the menopause ; but the largest proportion of cases occur between the ages of twenty and fifty. One or both ovaries may be affected.

If uninterfered with, the disease invariably proves fatal after a shorter or longer interval, usually within two or three years from the first development of an abdominal tumour, death occurring from gradual exhaustion due to interference with the functions of neighbouring viscera. But, in the great majority of instances, an earlier fatal termination is liable to result from some intercurrent complication or accident—such as rotation of the pedicle, inflammation of the cyst, rupture of its wall, &c., conditions which unless promptly dealt with, must inevitably hasten the patient's death.

Diagnosis.—The differential diagnosis of ovarian tumours from the numerous abdominal enlargements which may simulate them, is too extensive a subject to be treated of here. The following may, however, be enumerated as conditions possibly requiring elimination before a definite diagnosis of ovarian disease can be arrived at : 1. Obesity, oedema of the abdominal wall, tonic spasm of the recti muscles with hysterical tympanites (phantom tumour).

2. Stercoraceous accumulation, distended urinary bladder, retained menstrual fluid, distended gall-bladder. 3. Tumour of liver, spleen, or kidney, sarcoma of the abdominal glands. 4. Pelvic hæmatocele, abdominal or pelvic abscess. 5. Normal pregnancy, hydramnios, extra-uterine pregnancy, uterine fibromyoma, uterine fibro-cyst, hydro- or pyo-salpinx. 6. Hydro-nephrosis, hydatid cysts, pancreatic cysts, parovarian cysts. 7. Simple ascites, encysted dropsy of peritoneum, tuberculous disease, peritoneal cancer with ascitic fluid. The conditions enumerated in the last three of these groups are perhaps the most likely to mislead in forming an opinion.

In all cases of abdominal tumour, the patient should be examined undressed and lying upon her back with the shoulders somewhat raised and the knees drawn up. After carefully noting the salient points in the history of the case, such as the duration and rate of growth of the enlargement, its apparent seat of origin, the past and present condition of the menstrual function, &c., the Surgeon should proceed to determine the nature of the tumour by the systematic employment of the following means :—1. *Inspection* : Condition of the abdominal wall ; amount of distension ; shape and contour of the swelling, whether symmetrical or not, prominent anteriorly, or bulging laterally ; extent of downward movement visible on deep inspiration. 2. *Percussion* : Position and extent of resonance, whether strictly limited or diffused, altered or not by change of position on the part of the patient ; presence and nature of fluctuation, whether limited (encysted fluid), or general (free fluid). 3. *Palpation* : Size, outline, and consistence of the tumour ; its relative mobility ; solid or with fluid contents ; presence of nodular outgrowths. 4. *Auscultation* : Presence of the foetal heart in case of suspected pregnancy ; uterine souffle. 5. By *Vaginal* or *Rectal* examination combined with abdominal palpation it may be determined whether the tumour have a pelvic connexion or not ; and if so, whether it be uterine, tubal, or ovarian.

Tapping or aspiration of a fluctuant abdominal tumour of doubtful origin is occasionally resorted to with a view to ascertain its nature by examination of the fluid withdrawn ; and of late years an exploratory incision has been recommended in obscure cases as a more definite means of clearing up the diagnosis. This last procedure, although comparatively safe if performed with all due precautions, should by no means be rashly undertaken ; but if practised, the operator must be prepared at once to proceed to the removal of the tumour, should such a step be found advisable.

Treatment of Ovarian Tumour.—1. *By Medical Means.* These cannot possibly exercise any curative influence, or in any way retard the progress of the disease. The utmost that can be done by medical treatment in advanced ovarian disease is to attend to the general health, by relieving constipation and promoting free action of the kidneys pending the removal of the tumour.

2. *Tapping* in ovarian dropsy was formerly recommended as a palliative mode of treatment ; but experience has shown that after withdrawal of the fluid from a true ovarian cyst, re-accumulation invariably takes place, necessitating more and more frequent repetition of the tapping, if the treatment be persisted in, until the patient finally dies exhausted. The operation, therefore, not only holds out no prospect of cure ; but as a matter of fact, its adoption is usually the precursor of a more rapidly fatal termination to the case than would otherwise occur. For, in addition to the more immediate

risks attendant upon the procedure—such as wound of a vessel in the abdominal wall, in the subjacent omentum, or in the cyst-wall itself ; puncture of adherent intestine or urinary bladder ; escape of irritating ovarian fluid into the peritoneal cavity, &c.—tapping entails also certain remote dangers which render its adoption of very questionable advantage to the patient, even when undertaken as a means of temporary relief. Foremost among these may be mentioned adhesive peritonitis, inflammation of the cyst-wall, suppuration of its contents—conditions which must very seriously complicate any future attempt to extirpate the tumour. Even though none of these untoward events should result, yet the operation, unless performed with the strictest antiseptic precautions, is always liable to induce septic contamination of the cyst-fluids, a state of things which, although not necessarily leading to any obvious trouble at the time, will surely tend to diminish the patient's chance of recovery from a subsequent ovariectomy by exposing her to the risk of septicaemia. Finally, the puncture in the cyst-wall may from some cause or other remain unsealed, thus allowing free escape of ovarian fluid into the peritoneal cavity with all its attendant dangers, among which not the least is that of malignant infection of the peritoneum from a protruding papillomatous growth.

The above enumeration of the dangers incurred through tapping ovarian cysts is in accordance with the experience of those Surgeons who have had the fullest opportunities of judging of the results of this operation ; and it is not too much to say that the procedure is one to which recourse should be had only when it is rendered justifiable by exceptional circumstances.

As a means of relieving urgent dyspnoea, tapping is clearly applicable only to unilocular cysts, or to those multilocular tumours in which one cyst cavity largely predominates in size over its neighbours. When imperatively called for with this view, the operation should invariably be performed with antiseptic precautions, in order to obviate the risks of septic infection of the cyst-contents. The puncture may be made through the linea alba, as in the case of ordinary ascites ; but not unfrequently the tumour presents more distinctly at some other part of the abdominal wall, and the point selected may be varied accordingly, care being taken always to choose a spot free from intestinal resonance, and sufficiently remote from the pubes to avoid any possibility of puncturing the bladder which may be drawn up in front of the tumour.

Incision and Drainage is a method of treatment occasionally applicable with advantage in exceptional cases of universally adherent suppurating cysts, when attempted extirpation of the tumour would entail extreme risk to life, owing to the probability of rupture of the cyst-wall during its removal—an accident most likely to prove fatal, as involving the escape of irritating septic matter into the peritoneal cavity. The operation in such instances involves a short incision in the usual situation, of sufficient extent to enable the Surgeon to judge of the closeness of the parietal adhesions, and by puncture of the cyst to determine the putrid nature of its contents. After thorough evacuation and sponging-out of the cyst cavity a drainage-tube should be inserted, and the incision closed around it by means of sutures connecting the cyst with the margins of the opening in the abdominal wall. The subsequent management of the case involves frequent withdrawal of fluid from the tube by means of a

suitable syringe, and the use of some efficient antiseptic to prevent putrefaction of the discharges. Under this treatment, the cyst-cavity rapidly contracts, and may finally close entirely.

Other means of dealing with ovarian cysts have from time to time been suggested, all aiming at the same object, viz. that of inducing gradual contraction of the cyst and cohesion of its walls. But of the procedures advocated, the above described is the only one to be at all recommended, and this only in the exceptional instances alluded to. No operation, however, short of complete extirpation can be looked upon as surely curative; since, even after incision and drainage, followed apparently by complete contraction, it not uncommonly happens that secondary cysts develop in the wall or base of the original tumour; and eventually a multilocular growth may be substituted for what was apparently in the first instance a unilocular cyst. These measures have consequently, wherever possible, given way to the safer and far more certain procedure of ovariectomy.

Ovariectomy is probably the greatest triumph of modern Operative Surgery. In its original conception, as in its ultimate perfection, this operation reflects the greatest lustre on the British School of Surgery.

Its history is curious. Its progress was slow, and was marked by those oscillations in the judgment and the favour of the Profession which frequently precede the final establishment of a great advance in practice. The operation was originally proposed, and its practicability discussed in 1762, by William Hunter. It was strongly advocated and its practicability taught by John Bell, at a later period. It is said to have been performed in France, by L'Ammonier, in 1782, in a case of "scirrhus disease with abscess" of the ovary, the patient recovering. A pupil of John Bell—McDowell of Kentucky—first performed the operation in America in 1802; and in all operated thirteen times. In 1823, Lizars operated for the first time in this country. But the operation, though several times repeated, fell into discredit, in a great measure owing to the imperfection of the diagnosis of the cases in which it was done, and was not revived until 1836, when Jeaffreson of Framlingham practised it successfully through a small incision only an inch and a half long. From this operation we must date the revival of ovariectomy in Great Britain. This operation was followed by others performed by King of Saxmundham, Crisp of Harleston, and West of Tonbridge. The example of these provincial Surgeons was followed by their brethren in London, and the operation was practised by many, especially by Walne, F. Bird, and Baker Brown, but with very discouraging results; for of 162 cases collected by Robert Lee, in 60 the disease could not be removed, and of these 19 died; whilst of the remaining 102, 42 terminated fatally. Not only did these unfavourable results discourage the Profession, but a growing belief sprang up that this mortality, great as it was, did not by any means represent the whole extent of the fatal cases; and notwithstanding that C. Clay of Manchester continued to operate, ovariectomy was in great danger of falling into such disrepute as to be excluded from ordinary surgical practice. In 1857 appears for the first time in connexion with ovariectomy the name of a Surgeon, who was destined not only to revive ovariectomy, but to re-establish it firmly and definitively amongst the great operations in Surgery; for in December of that year Spencer Wells performed his first operation of this kind. This case, the first of a series of 1,000 cases completed by him in the year 1881,

led to a revival of the operation. In Spencer Wells's hands, ovariectomy assumed a new shape; its performance was guided by definite rules, the operative details were carefully worked out and systematized, and the after-treatment much improved. The results obtained showed a gradually increasing success, the proportion of recoveries rising from 66 to 89 per cent. in the cases operated on between 1857 and 1881. These results, admirable as they are, have been still further improved upon during late years by other well-known workers in this field of Surgery; and the procedure, formerly so fatal as to be pronounced unjustifiable, is now the most successful of all great surgical operations.

The wonderful improvement shown of late years in the death-rate of ovariectomy is in great measure to be explained by the very notable reduction in the number of deaths now recorded from septicaemia, a cause of mortality which formerly figured so largely in ovariectomy statistics.

The attainment of this result, apart from the employment of antiseptics which have so greatly influenced the progress of all surgical work during the past twenty years, is attributable to several causes, among which may be noted: 1. The gradual abandonment of the former practice of tapping ovarian cysts; 2. The general adoption of the intra-peritoneal method of dealing with the ovarian pedicle, in place of the extra-peritoneal treatment by means of the clamp, which was formerly used to a large extent; 3. The introduction of the plan of flushing out the abdominal cavity with warm sterilized water, as a substitute for the practice of cleansing the peritoneum by the use of sponges, followed or not by the employment of a drainage-tube.

In the days when the results of ovariectomy were much less good than they now are, the opinion generally held was in favour of postponing any surgical interference so long as the patient was tolerably free from pain and able to move about. Of late years, however, the increasing success of the operation, together with the fuller recognition of the serious risks entailed by delay in such cases, has led to the belief that an ovarian tumour should be removed as soon as its nature and connexions can be clearly ascertained, and its presence is beginning in any way to affect the patient's well-being.

Preparation of the Patient.—No special medical treatment is as a rule necessary, beyond attending to the state of the bowels. In the case, however, of a very large tumour of long standing, when the urine is scanty and highly concentrated, depositing quantities of mixed urates, benefit will be derived from the administration of full doses of citrate of potash or lithia during the forty-eight hours preceding operation, combined with the employment of a hot bath, should the skin be habitually dry and disinclined to act. Finally, a full dose of castor-oil or some equivalent aperient should be given the evening before, to be followed by an enema administered on the morning of the operation, to ensure thorough evacuation of the lower bowel.

The room selected for the operation and for subsequent occupation by the patient, must be thoroughly clean, airy, and well ventilated, if possible with an open fireplace. A trustworthy and competent nurse, accustomed to the use of the female catheter, and to the giving of nutrient enemata, should be chosen to take sole charge of the case; she, as well as all concerned in the operation, ought to be completely free from any taint of recent septic contamination.

All sponges and instruments, previously well cleansed, must be immersed in

a warm $2\frac{1}{2}$ per cent. solution of carbolic acid, and placed within easy reach of the operator's hand. The silk employed for ligatures, sutures, &c., should be thoroughly purified by soaking in a 5 per cent. solution of the acid for an hour or two before being used. It is an important rule, for obvious reasons, carefully to count the sponges and artery-forceps in use immediately before commencing the operation, so as to prevent the possibility of any subsequent doubt as to their number.

After the bladder has been emptied by means of a catheter, the patient in her night-dress and wearing a flannel bed-jacket and warm stockings, is placed upon the operating-table with her head and shoulders comfortably

Fig. 963.—Scissors for use in Abdominal Operations.

supported by pillows. Anæsthesia having been induced, the lower limbs wrapped in a blanket are secured by a broad strap buckled across just above the knees, while her hands are fastened on either side of the table. A thin mackintosh sheet, large enough to cover the patient entirely from the shoulders downwards, and having an opening in the centre four inches by six, coated around with adhesive material, is next applied to the abdomen, of which the skin, previously well cleansed with soap and water, should be sponged over with carbolic lotion before commencing the operation. The Surgeon, standing

Fig. 964.—Ovariotomy Trochar.

on the right side of the patient, is faced by his assistant on the opposite side of the table.

Operation.—No definite rule can be laid down as to the length of the incision, beyond stating that while necessarily proportionate to the size and nature of the tumour, it should in all cases be as limited as possible. A small cut, two or three inches long, extending in the mid-line to within an inch of the pubes, will suffice for the removal of any simple cyst; and, if necessary, may readily be prolonged upwards. All hæmorrhage from bleeding points in the abdominal wall having been arrested by the application of Wells's pressure-forceps, the peritoneum must be divided, care being taken to open it fairly; for, if adherent, it may readily be mistaken for the cyst-wall, and so stripped off the under surface of the abdominal muscles.

On exposing the tumour, any soft parietal adhesions in the immediate neighbourhood of the incision may be separated by the Surgeon's finger. The

growth, if cystic, should then be tapped with Wells's trochar (Fig. 964), care being taken to prevent the escape of any fluid into the abdominal cavity by fixing the edges of the puncture with the trochar-clamps, which enable the operator to extract the gradually collapsing cyst. Should this prove impracticable owing to the multilocular nature of the growth, the trochar must be

Fig. 965 —Nélaton's Cyst-Forceps.

carefully withdrawn after applying Nélaton's forceps (Fig. 965), and the puncture in the cyst-wall sufficiently enlarged to permit of the Surgeon introducing his hand for the purpose of breaking down the contents of the tumour. If still unable to extract it, he must prolong his incision upwards, and care-

Fig. 966.

Fig. 967.

Figs. 966, 967, 968.—Variously shaped Pressure-Forceps.

fully separate any parietal, omental, or intestinal adhesions which may be present, applying pressure-forceps (Figs. 966, 967, 968) as required to all bleeding points. Immediately after the extraction of the tumour, a flat sponge, squeezed thoroughly dry, should be introduced for the purpose of protecting the intestines and preventing their protrusion.

The pedicle is now examined and its connexion with the uterus clearly defined. As a rule it is most convenient to tie it before cutting away the tumour; but, if desirable, it may be temporarily secured with strong pressure-forceps during division, and then dealt with subsequently. Either of the two methods here represented may be employed for this purpose. That shown in Fig. 969 is the one most generally adopted. A single thread is first passed at a point just internal to the large plexus of veins in the outer edge of the pedicle, and securely tied so as to include the plexus, together with the ovarian artery which lies along this border; the pedicle is next transfixed centrally with a double ligature passed by means of the handled needle (Fig. 971), and is tied in equal halves, care being taken that the loops interlace at the seat of puncture. In the other method—shown in Fig. 970—the separate outer-edge ligature is usually dispensed with. The pedicle is transfixed as before, but with a needle carrying only a single thread, doubled upon itself; after withdrawal of the needle, one end of the ligature is brought half round the pedicle, passed through the projecting loop on the side opposite to its own point of exit, and thence carried onward to unite with the remaining end of the ligature round the other half of the pedicle, which is thus secured by a continuous twisted loop. Pressure-forceps are then applied to either border on the distal side of the ligatures, and the tumour is cut away. Finally, a single loop of stout silk is tied firmly round the stump, either exactly in or immediately behind the groove formed by the previous ligatures. All the threads should be cut short, and the pedicle be returned, without, however, removing the

Fig. 969.—Ligature of the Ovarian Pedicle (double loop).

Fig. 970.—Ligature of the Ovarian Pedicle (twisted loop).

Fig. 971.—Curved Pedicle-needle.

pressure-forceps, which are left on in order to facilitate the final examination of the stump before closing.

The condition of the remaining ovary should next be ascertained; and if diseased, it should be removed.

In dealing with tumours the base of which is implanted between the

expanded layers of the corresponding broad ligament—*intra-ligamentous* growths, so called in contradistinction to cysts connected with the uterus by a well-defined pedicle—resort must be had to the procedure known as *enucleation*. The tumour having been tapped and emptied, the investing layer of peritoneum is cautiously incised, and then gradually separated inch by inch from the base of the collapsed cyst until the main blood supply derived through the ovarian and uterine vessels is reached and clearly defined. These are now secured *en masse* by a double-loop transfixing ligature in the manner above described, and the cyst is cut away; any bleeding vessels on the inner surface of the remaining broad-ligament capsule are then tied, and its opposed surfaces are allowed to fall together at the bottom of the pelvis.

Parietal adhesions, unless of long standing, do not as a rule require ligature, temporary compression by forceps usually sufficing for the arrest of hæmorrhage. Should there, however, be general oozing from a somewhat extensive surface, the application of a sponge moistened with tincture of matricaria will serve readily to control it. Bands of pelvic adhesions must always be tied as near as possible to their seat of origin, and cut short. Omental and intestinal adhesions need careful management; the former should be dealt with either by transfixion and tying off in sections, or else by separate ligature of bleeding vessels; the latter, if extensive, may require to be laced by a fine continuous suture involving only the peritoneal coat of the intestine.

After all hæmorrhage has been controlled, a small soft sponge should be passed down to the bottom of the pelvis behind and also in front of the uterus for the purpose of removing any fluid or blood-clot that may remain in either one of these pouches. The pedicle is then finally examined to make certain that all is left secure; the forceps holding it are removed, and it is dropped in.

In cases of *ruptured cyst*, or where numerous and extensive vascular adhesions have been separated, the peritoneal sac may advantageously be flushed out with warm water, previously sterilized by boiling, introduced through a metal or stout glass tube directly to the more dependent portions of the abdominal cavity. This method of cleansing is far less irritating to the serous membrane than prolonged sponging; and, if thoroughly carried out, it effectually removes all blood-clot. The subsequent use of a drainage-tube is by no means essential, as any moderate amount of fluid left in the cavity is readily absorbed in the course of a few hours, and passed off through the kidneys.

The best material for suturing the abdominal incision is silk-worm gut, passed through the entire thickness of the parietes, including, of course, the divided edges of the peritoneum, at intervals of about half an inch. During the introduction of the stitches, the abdominal contents are to be protected by means of a small flat sponge.

Before closing the incision, all sponges and forceps are to be carefully counted, in order to make sure that none are missing.

Should drainage be deemed advisable, a glass tube of the required length is introduced to the bottom of Douglas's pouch from the lower end of the abdominal incision. The mouth of the tube is then covered with one or more well-carbolized sponges, enveloped in a rubber sheet with a perforation in its centre which fits closely around the everted lip of the tube (Fig. 972).

Finally, a dry antiseptic dressing is applied and kept in place by broad straps of adhesive plaster, over which a flannel binder is fastened securely round the patient's abdomen before placing her in bed.

After-Treatment.—Should sickness be troublesome, nothing need be given by the mouth for the first twenty-four or thirty-six hours beyond a little ice, plain soda-water, or brandy-and-water ; after which milk-and-water may be tried, to be succeeded, if retained, by plain bread-and-milk. In the meantime nutrient enemata of beef-tea with or without the addition of a tablespoonful of port wine, administered every three or four hours, will probably be of service ; the nurse being directed to introduce a rectal tube before each enema in order to facilitate the escape of flatus. The urine should be drawn off by the catheter four times daily for the first few days, or until the patient is able to pass it naturally. In a *drainage* case, renewal of the sponges, and withdrawal of fluid from the tube by means of a syringe with rubber tubing

Fig. 972.—Glass drainage-tube.

fitted to its nozzle, should be practised twice in each twenty-four hours until the tube is removed—usually at the end of the first forty-eight hours, when the opening left by it will readily close. If all be going well, ordinary light diet, such as milk-pudding, fish or chicken, may be allowed on the third or fourth day. Should there be much fever at any time, the application of an ice bladder to the head will soothe and tranquillize the patient, and promote reduction of the temperature. As a rule the bowels may be left undisturbed until they show some inclination to act, when they may be assisted by an enema. Finally, the stitches should be removed on the seventh or eighth day, and the patient may be allowed to leave her bed at the end of the second week, wearing a suitable abdominal belt.

After recovery from ovariectomy, the cure is usually complete.

The removal of one, or possibly of both, uterine appendages may, in exceptional instances of long-standing pelvic inflammatory troubles, justifiably be undertaken for the relief of persistent suffering associated with tangible disease of these organs. In such cases, the operation may prove to be of an exceedingly difficult and tedious nature, owing to the density and firmness of the adhesions in the pelvic cavity ; apart from this, however, the steps of the procedure required, and the details of the after-treatment, resemble in all essential features those above described in connexion with ovariectomy.

Pelvic suppuration may be broadly divided, according to its seat of origin, into *parametric* (subserous) and *perimetric* (intraperitoneal) formations of pus.

A **parametric** abscess usually originates in the substance of an inflammatory exudation developed between the folds of one or other broad ligament (pelvic cellulitis), or in a mass of hæmorrhagic effusion in the same situation (pelvic hæmatocele). If allowed to accumulate, the pus may find its way into the adjacent bowel or the urinary bladder ; or, extending downwards, it may effect its escape through the vaginal vault ; or, failing this, it may spread upwards towards the iliac fossa, ultimately pointing in the inguinal region or even over the iliac crest. Perforation of the abscess sac into the peritoneal cavity is an extremely rare accident. The proper *surgical treatment* of parametric suppura-

tion—as indicated by the occurrence of repeated chills combined with a characteristic temperature chart—depends upon the direction in which the abscess is pointing. If a distinct fluctuating swelling be detected in the *vaginal vault*, an exploratory puncture with a full-sized aspirator needle may be made in it after thorough cleansing and disinfection of the vagina ; should the pus be readily reached, the abscess sac is to be opened with scissors or the cautery knife to an extent sufficient to allow of the introduction of a double self-retaining rubber tube, through which irrigation can subsequently be practised, in order to ensure efficient drainage of the cavity. A parametric abscess rising into the *groin* should be opened by an incision parallel to, and about half an inch above, Poupart's ligament, so as to avoid injury to the peritoneum ; the cavity should be drained with antiseptic precautions.

A **perimetric** abscess is an encysted *intraperitoneal* collection of pus originating in connexion with suppurative (septic, or more rarely tuberculous) disease of one or both uterine appendages. The gradual formation of the abscess, due to repeated escape of small quantities of puriform matter from the imperfectly sealed ostium of an inflamed Fallopian tube (pyosalpinx), or to the presence of a small suppurating ovarian or tubo-ovarian cyst, accounts for the matting together of the pelvic viscera, which usually protects the general peritoneal cavity from infection. The proper *treatment* for such cases is *abdominal section*, in the performance of which great care must be taken at once to sponge away any purulent fluid which may be set free during the separation of pelvic adhesions. The diseased appendage should be cautiously enucleated from its pelvic attachments—if possible without being ruptured—until its uterine connexion can be defined, and ligatured previously to division. If the case be complicated by the existence of a rectal or vesical fistula, the subsequent use of a drainage-tube may be advisable for a few days.

Operations for the arrest of hæmorrhage in cases of **Ruptured Tubal Gestation**, by the removal of the damaged tube and ovary, usually present no special difficulty. After the broad ligament has been secured, the peritoneal cavity should be cleared of blood and clots by a thorough flushing out with a warm solution of common salt (1 drachm to the pint), and a drainage-tube be then inserted and retained for forty-eight hours.

Hernia of the Ovary.—It may happen that the ovary, on one or both sides, becomes displaced, and escapes from the pelvis through one of the openings which give passage to intestinal hernia. In three-fourths of the recorded cases (twenty-seven out of thirty-eight, according to Englisch of Vienna) the displacement has been inguinal. In nearly one-half of the cases it was congenital ; all these were instances of inguinal displacement ; and all the instances of double ovarian hernia were inguinal and congenital.

The *Causes* of the displacement in the adult are not easily ascertained. In the congenital cases it would seem as if an abnormal descent of the ovary took place, analogous to the descent of the testis in the male.

Symptoms.—Congenital ovarian hernia is nearly always irreducible ; while in most cases of acquired displacement of the ovary, it has been possible to return the tumour into the abdomen. The swelling is generally pyriform in the inguinal region, rounder in the femoral. There is no constant diagnostic symptom ; but in several instances it has been noticed that the hernia became tender on pressure, and larger during menstruation. At this time, also, rotation of the ovary may take place ; and, being attended with vomiting,

may lead the Surgeon to imagine that the case is one of strangulated hernia.

Strangulation of a hernia containing only the ovary is of rare occurrence. The condition has already been mentioned at page 838, where it was pointed out that the diagnosis may be difficult on account of the absence of the characteristic constitutional symptoms of strangulation. Thus, although there may be nausea, there is usually no actual vomiting, and although constipation is probably present, there is no real obstruction. Englisch showed that, of 20 cases in which symptoms of strangulation were present, a correct diagnosis was made in 7 only. Abscess or sloughing of the displaced ovary occasionally occurs.

In a case recently under the care of Bilton Pollard in University College Hospital, the end of the Fallopian tube was strangulated in a femoral hernia. The patient was thirty-seven years of age, and a swelling had been accidentally discovered in the left groin four days before her admission. On the following day the swelling became painful; the bowels continued to act; there was slight nausea, but no actual vomiting. The hernia was tense, rounded, and as large as a walnut. The sac contained clear fluid, and the swollen fimbriated extremity of the Fallopian tube, which was tightly nipped at the neck of the sac. The constriction was divided, and the tube returned into the abdomen.

Treatment.—So long as the hernia presents no special symptoms there is little or no occasion for interference, beyond the wearing of a properly fitted truss. If inflammation occur, the case must be treated on ordinary principles; and if the ovary suppurate, the abscess should be opened. When the ovary is very painful, or has become cystic, extirpation may be practised. If symptoms of acute strangulation occur, herniotomy must be performed, and as a rule removal of the ovary will be found necessary.
